Received 16 November 1998/Returned for modification 6 January 1999/Accepted 14 July 1999

In this study, we tested the efficacy of amphotericin B (AmB)-arabinogalactan (AmB-AG) conjugates for the treatment of experimental leishmaniasis. Chemical conjugation of AmB to a water-soluble, biodegradable, and biocompatible polymer could present many advantages over presently available AmB formulations. Two conjugates were tested, a reduced (rAmB-AG) form and an unreduced (uAmB-AG) form. In vitro, the drug concentrations which lower the values of parasites (for promastigotes) or infected macrophages (for amastigotes) to 50% of the untreated values (ED50) of uAmB-AG and rAmB-AG were 0.19 and 0.34 μg/ml, respectively, for Leishmania major promastigotes and 0.17 and 0.31 μg/ml, respectively, for amastigotes. The effect on Leishmania infantum-infected macrophages was more marked, with ED50 of 0.035 μg/ml for rAmB-AG and 0.027 μg/ml for uAmB-AG. In in vivo experiments, BALB/c mice infected with L. major were treated from day 2 onwards on alternate days for 2 weeks. Both conjugates, as well as liposomal AmB (all at 6 mg/kg of body weight) and Fungizone (1 mg/kg), significantly delayed the appearance of lesions compared to that in untreated mice. In addition, both conjugates, but not liposomal AmB, were significantly more effective than Fungizone. Subcutaneous injection of the conjugates (6 mg/kg) was significantly more effective than liposomal AmB in delaying the appearance of lesions. Higher AmB concentrations of up to 12 mg/kg could be administered by this route. When an established infection was treated, uAmB-AG was somewhat more effective than liposomal AmB. In summary, water-soluble polymeric AmB derivates were found effective and safe for the treatment of leishmanial infections. The conjugates, which are stable and can be produced relatively cheaply (compared to lipid formulations), can be used in the future for the treatment of leishmaniasis infections.
AmB derivatives over other drugs is further stressed by the recently reported lack of parasite resistance to AmB (9). In this study, we show the effects of two AmB-AG derivatives, a reduced (rAmB-AG) form and an unreduced (uAmB-AG) form, on leishmania promastigotes and amastigotes in vitro and on *Leishmania major* infection in BALB/c mice.

**Materials and Methods**

**AmB-AG synthesis.** AmB (a gift from Dumex, Copenhagen, Denmark) was conjugated to AG (a gift from Lalex International, St. Paul, Minn.) in two steps: first, AG was oxidized to dialdehyde AG with potassium periodate in water at 25°C and purified from the interfering oxidative anions (periodate and iodate) by passage through an ion-exchange column of Dowex-1 (Aldrich, Milwaukee, Wis.) in acetate form. Dowex-1 acetate was obtained by pretreating the commercial anion exchanger with 1 M acetic acid. The purified oxidized AG solution was dialyzed through a 12,000-molecular-weight cutoff dialysis tubing (Medicell International, London, United Kingdom) against deionized water for 48 h at 4°C and lyophilized to dryness. This purification step was critical because AmB is very sensitive to oxidation. In the next step, AmB was bound to the oxidized AG by formation of an imine bond between the primary amine bond of AmB and the aldehydes of the oxidized AG. Conjugation occurred in 0.1 M borate buffer solution, pH 11, for 48 h under constant stirring. A clear yellow-orange solution was obtained. The imine conjugate solution, with overnight stirring at room temperature. The average yield of this reaction was 90%. During the reduction process, a clear solution, pH 11, for 48 h under constant stirring. A clear yellow-orange solution was obtained. The imine conjugate was purified by dialysis and lyophilized to dryness. This purification step was critical because AmB is very sensitive to oxidation. In the next step, AmB was bound to the oxidized AG by formation of an imine bond between the primary amine bond of AmB and the aldehydes of the oxidized AG. Conjugation occurred in 0.1 M borate buffer solution, pH 11, for 48 h under constant stirring. A clear yellow-orange solution was obtained. The imine conjugate was purified by dialysis and lyophilized to dryness. The average yield was 80%. The imine (unreduced) conjugate (uAmB-AG) was reduced to a more stable amine form by the addition of sodium borohydride powder (1.1 M NaBH₄/mol of saccharide units in the polymer) to the imine conjugate solution, with overnight stirring at room temperature. The average yield of this reaction was 90%. During the reduction process, a clear yellow-orange to light yellow, was observed. The amine (reduced) conjugate (rAmB-AG) obtained was purified by dialysis and lyophilized as described above for the imine conjugate.

**Other AmB formulations used in this study.** Other AmB formulations used in this study were Fungizone (Bristol Myers Squibb), a mixed micelle formulation composed of AmB and sodium deoxycholate, and AmBisome, a unilamellar liposome formulation (Vestar, San Dimas, Calif.).

**Parasites.** *L. major* parasites, strain WR1045, were periodically isolated from BALB/c mice (Harlan Laboratories, Jerusalem, Israel) and maintained in RPMI 1640 culture medium supplemented with 20% fetal calf serum (Biological Industries, Beth Haemek, Israel) at 28°C, by weekly passage, for no more than 2 months. *L. infantum* parasites, strain LON 49 (MCAN/IL/94/LRC-639) were isolated from an infected dog near Jerusalem. The original isolate was frozen in aliquots which were thawed shortly before use. The parasites were maintained in culture under the same conditions as those of *L. major*.

In vitro effect on promastigotes. Parasites, after 3 or 4 days of growth, were washed and resuspended in fresh medium containing fetal calf serum to a concentration of 15 × 10⁶ promastigotes in 200 μl and distributed into flat-bottom wells (96-well plate; Nunc, Roskilde, Denmark). The plates were incubated at 28°C in a wet chamber in an atmosphere of 5% CO₂, 5% O₂, and 90% N₂. After 24 h, 0.5 μCi of [³H]thymidine (2 μCi/μmol; Nuclear Research Centre, Neger, Israel) was added to each well, the parasites were incubated for another 24 h, and then harvested on glass-microfiber filters. Radioactivity was measured in a liquid scintillation counter. Each treatment was performed in triplicate; the results are expressed as percent growth inhibition. [100 – cpm of wells with drug/ cpm of untreated wells] × 100 (cpm stands for counts per minute).

In vitro effect on amastigotes. Peritoneal macrophages were obtained from 10- to 12-week-old outbred mice previously stimulated for 4 or 5 days with 3% thioglycolate. The macrophages were distributed into 8-well slides (Nunc) to 2.5 × 10⁶ cells in 300 μl per well and incubated at 37°C and 5% CO₂ for 3 h in order to allow for cell adhesion. The supernatant was discarded, and promastigotes (8 × 10⁶ to 10 × 10⁶ per well) were added. After overnight incubation, fresh medium containing the AmB derivatives was added for an additional 24 to 48 h. At the end of this period, the wells were washed, fixed with methanol, and stained with Giemsa. Each treatment was done in duplicate wells; in each well, 100 macrophages and the number of amastigotes they contained were counted.

In vivo experiments. Female BALB/c mice (Harlan Laboratories) 6 to 10 weeks old, were injected subcutaneously (s.c.) in the base of the tail with 2 × 10⁴ stationary-phase promastigotes, six to eight mice per experimental group. Drug treatment was initiated 2 days after parasite injection or after the appearance of lesions (1 month after parasite injection) and was administered six times on alternate days. The drugs were given i.v. or s.c. in the abdominal area, as detailed for each experiment. Once a week, mice were checked for appearance of lesions, and lesion size was measured. To determine the diameter, the average was taken between the longest distance across the lesion and the length of the line bisecting this distance at a 90° angle. Mice were kept in a sterile pathogen-free animal facility throughout the experiments. In most cases, results are presented as number of mice with lesions at a given time, since the appearance of lesions is usually followed by a steady increase in lesion size.

Statistical analyses. Statistical evaluations were performed by Kaplan-Meier survival analysis. The log rank test was used to compare groups. Multiple comparisons were performed using Holm’s correction to the significance level. The SPSS program was used to run the analyses.

**Results**

Synthesis. AmB was conjugated to oxidized AG in borate buffer solution, pH 11, for 24 h at room temperature with an overall yield of 85%. Lower pH resulted in increased toxicity. Pure water-soluble conjugates containing 20% by weight of AmB were obtained as lyophilized powder. The reduced conjugate where the drug is attached by a stable amine bond was prepared by reducing the imine bond of the derivative using sodium borohydride. The structure of the imine conjugate is shown in Fig. 1.

**Effects of AmB-AG conjugates on parasites in vitro** (Table 1). First, AmB-AG was added to promastigote cultures, and its leishmanicidal effect was compared to that of Fungizone. The results using *L. major* show that the drug concentration which lowers the value of parasites (for promastigotes) or infected macrophages (for amastigotes) to 50% of the untreated values (ED₅₀) of Fungizone was lowest (0.02 μg/ml), while the ED₅₀ of uAmB-AG and rAmB-AG were 0.19 and 0.34 μg/ml, re-
spectively. The leishmanicidal effect on *L. infantum* was considerably higher: 0.01 μg/ml for Fungizone, 0.03 μg/ml for uAmB-AG, and 0.06 μg/ml for rAmB-AG.

Second, the effect of the derivatives on intracellular *L. major* amastigotes was determined in infected macrophage cultures. The percentage of infected macrophages was reduced by both conjugates (ED50s of 0.17 μg/ml for uAmB-AG and 0.31 μg/ml for rAmB-AG). The effect on *L. infantum*-infected macrophages was even more marked, with an ED50 of 0.035 μg/ml for rAmB-AG and 0.027 μg/ml for uAmB-AG.

Incubation of infected macrophages in the presence of the conjugates also reduced the number of amastigotes per macrophage: while most untreated macrophages contained one to six amastigotes, 85% of the macrophages treated with 0.25 μg of uAmB-AG per ml and 45% of the macrophages treated with 0.25 μg of rAmB-AG per ml contained no parasites (Fig. 2).

Effects of AmB-AG derivatives on the course of infection. BALB/c mice were injected in the rump with *L. major* promastigotes and treated on alternate days with 6 i.v. injections of Fungizone (1 mg/kg/day), AmBisome, or the AmB-AG conjugates (6 mg/kg/day), starting on day 2 after parasite injection. Mice were checked weekly for the appearance of lesions. Figure 3 presents the results of one typical experiment (of four performed, although not every experiment included all groups). Cumulative data of all experiments show that rAmB-AG (*n* = 23), uAmB-AG (*n* = 11), AmBisome (*n* = 16), and Fungizone (*n* = 14) significantly delayed the appearance of lesions (*P* < 0.0000) from that of untreated mice. In addition, rAmB-AG and uAmB-AG, but not AmBisome, were significantly more effective than Fungizone (*P* < 0.03 and 0.0001, respectively).

In another experiment, treatment by s.c. injection of the drugs was compared to i.v. treatment. AmBisome at 6 mg/kg had no significant effect when injected s.c. or i.v. However, s.c. injection of 12 mg/kg was more effective than the control (*P* < 0.0008) or than 6 mg/kg (*P* < 0.0017). uAmB-AG (6 mg/kg, i.v. or s.c.) was significantly more effective than the controls (0.0013 and 0.0003, respectively) or AmBisome given i.v. (0.0007 and 0.0023, respectively) and s.c. (0.0023 and 0.0006, respectively) (Table 2). Figure 4 summarizes the mean lesion area data for the mice from this experiment. The data show that, after 10 weeks, there is a marked difference not only in the number of mice with lesions but also in lesion size. It should be stressed that all the mice received the same parasite inoculum. The effects of treatment of an established infection with uAmB-AG and with AmBisome were examined. Treatment was started after lesions appeared, 1 month after parasite injection. While lesion size continued to increase in the control group, lesion size remained stable or decreased in the treated groups. The conjugate was slightly more effective than AmBisome (Fig. 5). However, the number of animals was too small to draw definite conclusions from this experiment.

### DISCUSSION

In recent years, AmB lipid formulations have been developed and have been shown to be effective and significantly less toxic than Fungizone. Three lipid formulations are now marketed for clinical use in many countries worldwide (12). The efficacy of these formulations has been evaluated in mouse models of VL. Liposomal AmB was about three times more active against *L. infantum* than Fungizone and was not toxic (19). In *L. donovani*-infected BALB/c mice, the overall efficacy

of AmBisome was equal to that of Amphocil and higher than that of Abelcet. Fungizone was the least effective AmB compound tested (17). In a murine *L. major* model for VL in which mice were treated starting 3 to 4 weeks after parasite injection, 25 and 12.5 mg of AmBisome per kg induced a reduction in lesion size, but 6.25 mg/kg was ineffective. In this model, 25 mg/kg, when injected s.c. close to the lesion, caused a small insignificant reduction in lesion size. Fungizone (1 mg/kg) was inactive both i.v. and s.c. (21).

In all studies with mice, as well as with humans (8), all lipid formulations must be repeatedly administered i.v. in order to be effective. An additional disadvantage of the lipid formulations, which may prevent their widespread use, is their high cost to the patient (7).

In this study, we have evaluated the efficacy of a new type of water-soluble AmB compound for the treatment of experimental leishmaniasis based on the conjugation of AmB to a highly branched polysaccharide, which may overcome some of the disadvantages of lipid AmB formulations.

The main difference between the conjugated drug and the lipid-based formulations is that the latter are particulate systems that may be unstable physically and chemically and they are difficult to sterilize by filtration. The conjugated AmB, however, is water soluble, easily sterilized by filtration, and physically and chemically stable as lyophilized powder and as reconstituted solution. The conjugated AmB-AG, loaded with up to 40% drug by weight, has a molecular weight of 20,000, is highly water soluble (>10% [wt/vol] in water for injection) and biodegradable, and is thus expected to be safely eliminated from the body.

The preparation of the conjugate involves two independent steps which are conducted at room temperature using water

* Treatment was started 2 days after injection of parasites.
The first step is the formation of pure oxidized AG which is conducted by dissolving AG into a solution of the oxidizing agent, periodate, and allowing the oxidation to occur for a few hours at room temperature. The oxidized AG with about 38% of its saccharide units oxidized to dialdehydes is purified by ion-exchange chromatography to remove excess periodate and lyophilized to a powder that is stable at refrigeration for at least 1 year. The conjugation step is conducted at room temperature in borate buffer solution, pH 11, at which the drug has some solubility. The reaction solution is filtered and dialyzed to remove unreacted drug and salts and lyophilized to form a yellow powder which is easily reconstituted prior to use. If the reduced conjugate is desired, the conjugate solution is reacted with excess sodium borohydride prior to dialysis and lyophilization. As described, the method of preparation and reagents are simple and inexpensive, which may make this product available for treating leishmania infections in poor countries.

Both AmB-AG conjugates were initially prepared and investigated for treating fungal infections. Both were found very effective against candidiasis and Cryptococcus infections in mice with the unreduced conjugate being more effective, as described elsewhere (10). Studies conducted on mice indicated that both conjugates are at least as safe as AmBisome with maximal tolerated doses in the range of 50 mg of AmB equivalents per kg or 250 mg of the conjugated product per kg (10).

The two AmB-AG derivatives evaluated in this study, the reduced (rAmB-AG) and unreduced (uAmB-AG) forms were consistently more effective than Fungizone and often also more effective than AmBisome for the treatment of leishmaniasis infection, when treatment was started 2 days after parasite injection (Fig. 3 and 4). The unreduced conjugate was also more effective than AmBisome for the treatment of an established leishmanial infection (Fig. 5).

In both in vivo and in vitro experiments, uAmB-AG was more effective than rAmB-AG against L. major. The higher efficacy of this conjugate may be related to the fact that the imine bond of the unreduced form is less hydrolytically stable than the amine bond of the reduced form, thus making AmB more easily released from the carrier molecule. If this is the case, the data presented here suggest that the performance of the imine-conjugated AmB-AG may be affected by similar delivery systems such as amphiphile-based assemblies containing AmB (6, 13).

Upon comparison of the effects of AmB-AG on L. major and L. infantum, it appears that the ED$_{50}$ for L. infantum is lower than the ED$_{50}$ for L. major for both promastigotes and amastigotes. Since the same is true for Fungizone (Table 1 and results not shown), and for pentavalent antimonial drugs (3), this is probably due to an intrinsic difference between L. major and L. infantum rather than to a characteristic of the AmB-AG conjugate. Regarding the effects of AmB-AG on amastigotes and promastigotes, the ED$_{50}$ for amastigotes was lower than for promastigotes. Similar results were reported for Fungizone and AmBisome (21). Taken together, these data suggest that AmB administered as a polysaccharide conjugate does not interfere with the known mechanism of AmB administered as an amphiphile-based assembly.

We have shown here that higher doses of AmB-AG can be administered by the s.c. as well as by the i.v. route. The fact that fewer mice developed lesions after s.c. injection with higher doses of uAmB-AG stresses the advantage of s.c. injections. In addition to allowing for the administration of higher drug dosages, the s.c. route represents a method of slow drug release, thus lowering the toxicity of AmB.

In summary, water-soluble polymeric AmB derivatives were found effective and safe for treating leishmanial infections in mice. Such treatment could also be used for animal and human infections.
