Mycobacterium avium is a common cause of systemic bacterial infection in patients with AIDS. Infection with M. avium has been linked to bacterial colonization of domestic water supplies and commonly occurs through the gastrointestinal tract. Acanthamoeba castellanii, a waterborne protozoon, may serve as an environmental host for M. avium. It has been shown that growth of M. avium in amoebae enhances invasion and intracellular replication of the bacteria in human macrophages and intestinal epithelial cell line HT-29 as well as in mice. We determined that growth of M. avium within A. castellanii influenced susceptibility to rifabutin, azithromycin, and clarithromycin. No significant activity against M. avium was seen with rifabutin, azithromycin, and clarithromycin when used to treat monolayers on both day 1 and day 4 after infection. When tested in a macrophage-like cell line (U937), all compounds showed significant anti-M. avium activity. Growth of M. avium in amoebae appears to reduce the effectiveness of the antimicrobials. These findings may have significant implications for prophylaxis of M. avium infection in AIDS.

Disseminated infection caused by organisms of the Mycobacterium avium complex is a common finding in patients with advanced stages of AIDS (11, 12). Recent evidence supports the concept that M. avium’s major route of infection in this population of patients is through the intestinal tract (9; F. Torriani, J. N. Maslow, R. Kornbluth, R. D. Arbeint, J. A. McCutchan, P. Hasegawa, L. Keays, D. Havlir, and The California Collaborative Treatment Group, Abstr. 35th Intersci. Conf. Antimicrob. Agents Chemother., abstr. I91, p. 221, 1995). M. avium has been shown to colonize the intestinal lumen before dissemination (9; Torriani et al., 35th ICAAC).

In addition, studies with experimental mice indicated that bacterial load in mice infected with M. avium increased efficiency compared with that of M. avium in amoebae. These findings may have significant implications for prophylaxis of M. avium infection in AIDS.
rubber policeman. The resulting suspension was centrifuged at 800 \times g for 10 min, and the cells were resuspended in high-salt buffer \((7, 8)\) to a concentration of \(2 \times 10^5\) cells/ml. To prepare monolayers, a 24-well tissue culture plate was used. Acanthamoeba was seeded and incubated for 1 h to allow the amoebae to adhere to the plastic. The Acanthamoeba monolayers were then infected with \(10^6\) bacteria and incubated for 4 h at 37°C. After the period of infection, monolayers were washed twice with HBSS to remove extracellular bacteria. The removal of extracellular bacteria by this method has been established previously \((6, 8)\).

Baseline wells were lysed by adding 1 ml of 1% Triton

FIG. 1. Activities of rifabutin (RIF), clarithromycin (CLM), and azithromycin (AZM) against intracellular \textit{M. avium} were examined according to two different protocols. (A) \textit{A. castellanii} and macrophages (U937) were infected as described in the text, and treatment was initiated 4 h after infection; asterisks show that \(P\) was <0.05 for the comparison between the number of bacteria in the untreated control and the number of organisms within macrophages following all three antibiotic treatments. No statistically significant difference was observed among the Acanthamoeba groups. (B) \textit{A. castellanii} was infected with \textit{M. avium}, and 4 days after infection, treatment with antimicrobials was initiated and continued for 4 more days. No statistically significant difference was observed between the untreated control and the groups treated with antimicrobials.
X-100. Previous study has demonstrated that *M. avium* is resistant to this concentration of Triton X-100 (8). Lysed monolayers were diluted in water, and the number of viable bacteria was determined as previously described (8).

Monolayers of macrophage cell line U937 (10^6 cells) were infected as described for amoebae, except that macrophages were lysed by incubating the cells with sterile water for 10 min (4).

The monolayers used in experimental assays were monitored as previously described to ensure that all the monolayers had approximately the same number of cells (4, 8). Infection of *Acanthamoeba* monolayers with *S. aureus* (multiplicity of infection of 10) was carried out for 1 h at 37°C with a subsequent wash (three times) of extracellular bacteria with HBSS.

Rifabutin was provided by Farmitalia Carlos Erba (Milan, Italy), azithromycin was provided by Pfizer Research Laboratories, Inc. (Groton, Conn.), and clarithromycin was supplied by Abbott (Chicago, Ill.). The antimicrobials were prepared as recommended by the manufacturers. Rifabutin was dissolved in ethanol; azithromycin and clarithromycin were dissolved in dimethyl sulfoxide. All compounds were subsequently diluted in ethanol; azithromycin and clarithromycin were dissolved in dimethyl sulfoxide. All compounds were subsequently diluted in HBSS to the desired concentration. The MICs of rifabutin, azithromycin, and clarithromycin for *M. avium* strain 101, as determined by the radiometric method (BACTEC; Johnston Laboratories, Cockeysville, Md.) as described previously (4), were 2, 32, and 4 µg/ml, respectively (data not shown).

To compare the responses of *M. avium* to treatment with antimicrobials when within either amoebae or macrophages, infected monolayers were treated from day 1 postinfection with rifabutin (2 and 4 µg/ml), clarithromycin (2 and 4 µg/ml), and azithromycin (2 and 4 µg/ml) for 4 days with the drug and medium was replenished daily. These concentrations had been shown to be bacteriostatic for intracellular *M. avium* (12). On day 5, cells were lysed and the viable bacteria in the lysates were quantitated.

As a variant of the assay, *Acanthamoeba* monolayers were infected with *M. avium* for 4 h, extracellular bacteria were removed by washing, and the monolayers were kept for 4 days before the initiation of treatment with antimicrobials (Fig. 1B). *Acanthamoeba* monolayers were treated for 4 days and then lysed. Monolayers infected with *S. aureus* for 1 h were treated with antimicrobials for 4 h at 37°C and then lysed with 1 ml of 1% Triton X-100.

In order to determine whether intracellular *M. avium* that showed resistance to drug treatment when inside amoebae would have a resistant phenotype, *Acanthamoeba* was infected with *M. avium* 101 for 4 days and then lysed. Released bacteria were cultured on 7H11 agar for 8 days, and then their susceptibility to antibiotics was determined as described previously (4).

The assays were repeated three times, and the results were expressed as means ± standard errors of the means. The statistical significance of the differences between experimental groups and control at the same time point was analyzed by the Mann-Whitney nonparametric test.

*M. avium*-infected *A. castellanii* monolayers treated with rifabutin, clarithromycin, or azithromycin from the day after infection, for 4 days, showed no significant reduction in CFU per milliliter (Fig. 1A). Similarly, monolayers in which treatment was delayed for 4 days also showed no reduction in the number of intracellular bacteria compared with untreated controls (Fig. 1B). In contrast, all three compounds were found to be significantly active against *M. avium* within U937 macrophages. Treatment with rifabutin (both at 2 and at 4 µg/ml) resulted in approximately 97% inhibition of growth after 4 days (*P* < 0.05). Clarithromycin when added at 2 µg/ml was associated with 93% inhibition, and at 4 µg/ml it led to 96% inhibition of growth of intracellular *M. avium*, while azithromycin at 4 µg/ml resulted in an 88% inhibition of growth of intracellular bacteria. Only data for 4 µg/ml are shown (Fig. 1A).

The lack of effect of antimicrobials could be due to an impaired ability to enter *Acanthamoeba*. To determine whether antimicrobials could penetrate *A. castellanii* and not be degraded intracellularly, we infected *A. castellanii* monolayers with a clinical strain of *S. aureus* and treated the monolayers with rifabutin (2 or 4 µg/ml), clarithromycin (2 or 4 µg/ml), or azithromycin (2 or 4 µg/ml). As shown in Fig. 2 (only data for 4 µg/ml are shown), all the concentrations used of the three compounds were associated with significant killing or inhibi-
tion of growth of the intracellular S. aureus. Rifabutin was bactericidal while clarithromycin and azithromycin were bacteriostatic (rifabutin MIC, 0.5 μg/ml; clarithromycin MIC, 0.5 μg/ml; and azithromycin MIC, 2 μg/ml), showing that activity can be observed within amoebae. We then used 10 and 20 μg of the antimicrobials per ml in the medium (Fig. 3). The effect of the compounds on the bacterial growth was similar to the effect obtained with concentrations of 2 and 4 μg/ml (Fig. 1A). Even the effect of 2 or 4 μg/ml was small if the inoculum used was greater than 10^4 organisms (data not shown).

To rule out the presence of selection of a resistant phenotype of Acanthamoeba, M. avium was used to infect Acanthamoeba, then retrieved from amoebae, and grown on culture medium in vitro and subsequently the MIC was determined. Table 1 shows that M. avium passaged in vitro is still susceptible to the drugs used.

We showed that M. avium living within Acanthamoeba has increased resistance to antimicrobials usually prescribed as prophylaxis for M. avium disease in AIDS patients, such as rifabutin, clarithromycin, and azithromycin (13), compared with M. avium organisms residing within U937 macrophages. This finding could be intuitively explained by either decreased uptake of the antimicrobials into the amoebae in comparison with the uptake of macrophages, inactivation of the compound within amoebae, or even a change in the phenotype of the bacterium. If a change in the M. avium phenotype is the explanation for the resistance phenomenon, it must occur early in the infection, because Acanthamoeba-infected monolayers showed resistance to rifabutin and macrolides both when the monolayer was exposed to the antibiotics 4 h after infection and when intracellular bacteria were allowed to adapt to the intracellular environment for 4 days before the initiation of therapy. This hypothesis has some support from previous data showing that L. pneumophila undergoes surface changes once inside Acanthamoeba polyphaga (2), becoming more resistant to biocide inactivation (1) including chlorine treatment (J. S. Navratil, R. H. Palmer, S. States, J. M. Kuchta, R. M. Wadowsky, and R. B. Yee, Abstr. 90th Annu. Meet. Am. Soc. Microbiol. 1990, abstr. Q-82, p. 302, 1990) than cells grown in vitro.

Because amoebae live in natural sources of water and therefore are constantly exposed to hypoosmolarity, the cytoplasmic membrane is more resistant to decrease in osmolarity and the amoeba is capable of controlling the effects of osmolarity either by encysting or by pumping salts across the membranes. These two properties may be associated with decreased permeability to drugs as well as decreased intracellular concentration.

Enhanced resistance of M. avium to antimicrobials either by location within amoebae or by passage within amoebae may impact the efficacy of the prophylactic use of antimicrobials.

^a MIC99, MIC at which 99% of the isolates tested are inhibited; MIC99.9, MIC at which 99.9% of the isolates tested are inhibited. The data represent the numbers obtained in a representative experiment (BACTEC assay was carried out twice). The numbers were obtained by using the T100 method as previously described (4).

^b P > 0.05 compared with the MICs of antibiotics against M. avium grown in amoebae and passed on 7H11 medium.
Using concentrations of antibiotics that are active against *M. avium* in human macrophages (12), we have determined that infection of *Acanthamoeba* by *M. avium* results in decreased activity of rifabutin and macrolides against the bacterium, although there is no evidence that the intracellular bacterium, when released from the amoeba, will maintain a phenotype of resistance to antimicrobials for several generations. The mechanism of bacterial resistance and the hypothetical impact on prophylaxis of *M. avium* disease in AIDS patients warrant further investigation.

We thank Karen Allen for preparing the manuscript.
