In experimental meningitis a single dose of gentamicin (10 mg/kg of body weight) led to gentamicin levels in around cerebrospinal fluid (CSF) of 4 mg/liter for 4 h, decreasing slowly to 2 mg/liter 4 h later. The CSF penetration of gentamicin ranged around 27%, calculated by comparison of areas under the curve (AUC in serum/AUC in CSF). Gentamicin monotherapy (−1.24 log10 CFU/ml) was inferior to vancomycin monotherapy (−2.54 log10 CFU/ml) over 8 h against penicillin-resistant pneumococci. However, the combination of vancomycin with gentamicin was significantly superior (−4.48 log10 CFU/ml) compared to either monotherapy alone. The synergistic activity of vancomycin combined with gentamicin was also demonstrated in vitro in time-kill assays.

The treatment of pneumococcal infections has been complicated by the widespread spread of penicillin-resistant strains (3). In life-threatening infections, particularly in meningitis, penicillin is ineffective even against strains with intermediate resistance, and penicillin resistance is often associated with resistance to other β-lactam antibiotics. Because of treatment failures observed with cephalosporin monotherapy (4, 14), a combination of vancomycin with a broad-spectrum cephalosporin (ceftriaxone or cefotaxime) is usually recommended for treatment of meningitis with resistant strains (12).

However, in case of β-lactam allergy, the choice of an adequate therapy is more challenging. Little is known about the role of gentamicin in meningitis due to penicillin-resistant pneumococci. The aim of this study was to test gentamicin as monotherapy and in combination with vancomycin against penicillin-resistant strains in experimental meningitis. The standard treatment consisted of vancomycin combined with ceftriaxone.

MATERIALS AND METHODS

Rabbit meningitis model. The meningitis model, originally described by Dacey and Sande (6), was slightly modified. The experimental protocol was accepted by the local ethical committee (Veterinäramt des Kantons Bern). Briefly, young New Zealand White rabbits weighing 2 to 2.5 kg were anesthetized by intramuscular injections of ketamine (30 mg/kg of body weight) and xylazine (15 mg/kg), and were immobilized in stereotactic frames for induction of meningitis. An inoculum containing approximately 106 CFU of penicillin-resistant pneumococci serotype 6 was directly injected into the cisterna magna. The pneumococcal strain had originally been isolated from a patient with pneumonia at the University Hospital of Bern, Bern, Switzerland. ATCC 6633 was used as a test strain for vancomycin and gentamicin (7). The intra- and interday variability of this method was less than 10%. The limits of detection were 0.5 mg/liter for vancomycin, and 0.10 mg/liter for gentamicin.

In vitro assays. The pneumococcal strain was grown in C Y medium (8) to an optical density at 590 nm of 0.3 and then diluted 40-fold to 104 CFU/ml, corresponding to the CSF bacterial titer in rabbits before initiation of therapy. Gentamicin was added in concentrations corresponding to one time the MIC (4 mg/liter), corresponding to levels achieved in the CSF; vancomycin was added in concentrations ranging from one to two times the MIC. Combination therapy with vancomycin and gentamicin was also tested. Bacterial titer were determined at 0, 2, 4, 6, and 8 h by serial dilution of samples; plated on agar plates containing 5% sheep blood; and incubated overnight at 37°C for 24 h. Experiments were performed in triplicate, and results are expressed as means ± standard deviation. Synergy was defined as bactericidal effect of a drug combination greater than 2-log killing over the most active drug alone.

RESULTS AND DISCUSSION

We decided to administer gentamicin in a single dose in order to produce higher levels in CSF than were achievable by
conventional multiple daily dosing during the major part of the treatment period (1). A single injection of gentamicin led to peak levels in serum of around 33 mg/liter, declining to 2 mg/liter 8 h later. The peak levels in CSF ranged around 4.3 mg/liter, and the trough levels were around 2.2 mg/liter at the end of the treatment period. The CSF penetration by gentamicin was calculated for each animal by comparison of serum and CSF areas under the curve (AUC) (Systat software; SSPP Inc., Evanston, Ill.). In our model, the penetration of gentamicin into the CSF was 27% ± 7%, confirming previous studies (1). The CSF gentamicin levels remained around the MIC (4 mg/liter) for approximately 4 h (Fig. 1). The peak concentrations of gentamicin in serum were similar to those observed in humans after one single-dose regimen (10). The CSF vancomycin levels ranged between 3.5 and 1.5 mg/liter, remaining above the MIC during the entire treatment period (data not shown), and corresponded to levels achieved in humans (2, 11).

The killing rates of the different regimens are summarized in Table 1. Gentamicin monotherapy produced a negligible antibacterial activity due to the pharmacokinetic profile of a single dose of gentamicin leading to CSF gentamicin levels around the MIC only during half of the treatment period (Fig. 1). In our experimental model, vancomycin as either monotherapy or combined with ceftriaxone showed antibacterial activities comparable to those described previously (8, 5, 13). It is interesting to note that the addition of vancomycin to gentamicin led to a synergy and significantly increased the killing rate of gentamicin, producing an antimicrobial activity comparable to that of the standard regimen (vancomycin plus ceftriaxone). The synergistic activity between vancomycin and gentamicin was also found in vitro in time-kill assays over 8 h. In this experimental setting, a gentamicin concentration of one time the MIC (4 mg/liter) was selected, corresponding to levels achieved in CSF of rabbits.

Addition of vancomycin in higher concentrations (two times the MIC) clearly resulted in synergy and sterilized the cultures after 6 h (Fig. 2). Similar results were obtained with another penicillin-resistant pneumococcal strain (KR4) in vitro (MIC of penicillin, 4 mg/liter; MIC of gentamicin, 4 mg/liter) (data not shown). Improved activity of gentamicin in vitro by addition of vancomycin has already been described, without reaching an extent qualifying as synergy (9). The reasons for the synergy observed in vitro by increasing the vancomycin dose is not clear, but is reminiscent of the synergy between β-lactamases and β-lactamase inhibitors.

antibiotics as cell wall-active antibiotics and aminoglycosides observed in enterococci. A synergy between amoxicillin and gentamicin against resistant pneumococci has already been observed in a mouse pneumonia model (7).

Based on our data, it is obvious that gentamicin cannot be recommended as monotherapy for pneumococcal meningitis due to resistant strains because of its insufficient penetration into the CSF and its narrow safety profile. However, gentamicin combined with vancomycin could be a conceivable alternative regimen, especially in case of β-lactam allergy. These data deserve further evaluation.

FIG. 2. Solid squares represent killing rates of vancomycin (Vanco2XMIC [0.25 mg/liter]), gentamicin (Genta1XMIC: [4 mg/liter]), and the combination of the two antibiotics (Genta1X MIC + Vanco 2XMIC) in vitro. Open squares represent untreated controls. The experiments were performed in triplicate, and the results are expressed as means ± standard deviations. * P < 0.05 versus either single drug therapy.
