Functional Antibodies Targeting IsaA of *Staphylococcus aureus*
Augment Host Immune Response and Open New Perspectives for Antibacterial Therapy

*Staphylococcus aureus* is the most common cause of nosocomial infections. Multiple antibiotic resistance and severe clinical outcomes provide a strong rationale for development of immunoglobulin-based strategies. Traditionally, novel immunological approaches against bacterial pathogens involve antibodies directed against cell surface-exposed virulence-associated epitopes or toxins. In this study, we generated a monoclonal antibody targeting the housekeeping protein IsaA, a suggested soluble lytic transglycosylase of *S. aureus*, and tested its therapeutic efficacy in two experimental mouse infection models. A murine anti-IsaA antibody of the IgG1 subclass (UK-66P) showed the highest binding affinity in Biacore analysis. This antibody recognized all *S. aureus* strains tested, including hospital-acquired and community-acquired methicillin-resistant *S. aureus* strains. Therapeutic efficacy *in vivo* in mice was analyzed using a central venous catheter-related infection model and a sepsis survival model. In both models, anti-IsaA IgG1 conferred protection against staphylococcal infection. *Ex vivo*, UK-66P activates professional phagocytes and induces highly microbicidal reactive oxygen metabolites in a dose-dependent manner, resulting in bacterial killing. The study provides proof of concept that monoclonal IgG1 antibodies with high affinity to the ubiquitously expressed, single-epitope-targeting IsaA are effective in the treatment of staphylococcal infection in different mouse models. Anti-IsaA antibodies might be a useful component in an antibody-based therapeutic for prophylaxis or adjunctive treatment of human cases of *S. aureus* infections.
recognizing IsaA was investigated. Both infection models show that passive anti-IsaA antibody application significantly reduces the bacterial burden in host tissues compared to that in untreated animals. In addition, anti-IsaA immunotherapy triggers highly microbial reactive oxygen metabolites by phagocytes and killing of \textit{S. aureus}.

Overall, the data presented within the study prove that the staphylococcal immunodominant antigen IsaA is a promising candidate for antibody-based therapy that could significantly improve the outcome of \textit{S. aureus} infection in humans.

**MATERIALS AND METHODS**

**Monoclonal antibody production.** Murine monoclonal antibodies were generated by the standard protocol of Synaptic Systems (Goettingen, Germany), using an enzyme-linked immunosorbent assay (ELISA) and Western blot screening. Briefly, three 8- to 10-week-old female BALB/c mice were immunized over a period of 17 days with the purified recombinant IsaA (rIsaA) protein. Cells from knee lymph nodes were fused with the mouse myeloma cell line P3X63Ag.653 (ATCC CRL-1580). The hybridoma elected in this study was cloned twice by limiting dilution. The monoclonal antibody was determined to be of the IgG1 subclass. The IgG1 antibody solution was purified by protein G flow-fast affinity chromatography as described elsewhere (17). Purified anti-IsaA IgG1 MAb (UK-66P) and murine isotype control antibody (IC) were further used.

**Biosensor Measurements.** To determine the affinity of the monoclonal antibody UK-66P to IsaA, the kinetics of binding of rIsaA to immobilized antibody was determined by means of label-free surface plasmon resonance using a Biacore 2000 system (GE Healthcare Europe GmbH, Freiburg, Germany). Reversible immobilization of the antibody UK-66P was performed using an anti-mouse Fc antibody covalently coupled in high density (18,700 resonance units [RU]) to a CMS sensor surface according to the manufacturer’s instructions (mouse antibody capture kit; GE Healthcare). The average amount of captured antibody UK-66P on the anti-mouse Fc surface corresponds to about 640 RU. A blank anti-mouse Fc surface was used as a control surface for monitoring unspecific binding and performing reference subtraction. Interaction analyses were performed using HBS-EP buffer (10 mM HEPES, pH 7.4, 150 mM NaCl, 3 mM EDTA, 0.005% Tween 20). Sensorgrams were recorded at a flow rate of 30 \( \mu l/min \) at 25°C. Association and dissociation times were set to 3 and 15 min, respectively. The anti-Fc capturing surfaces were regenerated after each cycle by using short pulses of 10 mM glycine, pH 1.7. Affinities (equilibrium dissociation constant \( K_d \)) and rate constants for association (\( k_a \)) and for dissociation (\( k_d \)) were calculated using BIAevaluation software 4.0.1, fitting the obtained sensorgrams to a 1:1 Langmuir binding model.

**Bacteria.** The wild-type \textit{S. aureus} strain MA12 and its isogenic IsaA insertion mutant strain MA12 \( \Delta a:s.a. \) (EM) (MA12 \( \Delta a:s.a. \)) were used throughout. The IsaA mutant strain served as an internal control for UK-66P specificity within the expected range of binding of UK-66P to IsaA. The protein \( \Delta a:s.a. \) (Cowan I \( \Delta a:s.a. \) (DU 5889) was used to test cross-reactivity of UK-66P. The strains ANS46 (staphylococcal chromosome metcillin resistant type III [SCCmec III]), BK2464 (SCCmec II), HDE288 (SCCmec IV), MUS05 (vancomycin-resistant \textit{S. aureus} [VRSA]), MW2 (community-acquired methicillin-resistant \textit{S. aureus} [CA-MRSA]), and EMSRA-15 (epidemic MRSA) were used as controls for binding experiments. The strain USA300 (CA-MRSA) was also used for survival analysis. Single colonies of the respective strain were used to inoculate a 25-ml 2\( \times \) YT (16 g tryptone, 10 g yeast extract, 5 g NaCl) broth culture overnight at 37°C. The culture was washed in phosphate-buffered saline (PBS), and serial dilution was performed to obtain a concentration of 10\(^6\) or 10\(^7\) CFU, which was confirmed by quantitative culture analysis. The bacteria were suspended in 0.1 ml or 0.5 ml of physiologic NaCl solution for infection experiments (see below).

**Indirect immunofluorescence assay.** \textit{S. aureus} MA12, its isogenic IsaA insertion mutant strain MA12 \( \Delta a:s.a. \), and Cowan I \( \Delta a:s.a. \) were grown in Trypticase soy broth (TSB) to mid-log phase (optical density at 600 nm [OD\(_{600}\)] of 0.5), and 1 ml of the culture was centrifuged for 5 min at 13,000 \( \times g \). The washed bacterial sediment was suspended in 1 ml PBS (10 mM sodium phosphate [pH 7.2], 0.15 M sodium chloride). An aliquot of the cell suspension (100 \( \mu l \)) was mixed with UK-66P in PBS and incubated at room temperature for 15 min. The fluorescence isothiocyanate (FITC)-conjugated goat anti-mouse IgG (H+L) (Di-anova, Hamburg, Germany) was added, and the mixture was incubated at room temperature for 30 min in a dark moisture chamber. After the bacteria were washed three times with 200 \( \mu l \) of PBS, the cells were suspended in 100 \( \mu l \) of PBS and viewed with a Zeiss Axiosplan epifluorescence microscope. The images were captured with a low-light Intas MP Focus 5000 camera. The fluorescence and the phase-contrast images were processed in Adobe Photoshop CS2.

**Quantitative determination of neutrophil activation and oxidative burst.** For the quantitative determination of murine neutrophil oxidative burst, the commercially available flow cytometry-based Phagoburst test kit was used according to the manufacturer’s instruction (Orpegen Pharma, Heidelberg, Germany). The Phagoburst assay allows the determination of neutrophils that oxidize the fluorescent substrate dihydrorhodamine 123 (DHR123). For oxidative burst analysis, heparinized blood was drawn from mice under general anesthesia by femoral vein puncture. Wild-type \textit{S. aureus} strain MA12 and IsaA mutant strain MA12 \( \Delta a:s.a. \) were cultured in LB medium at 37°C and harvested in mid-logarithmic phase. Blood was washed twice with PBS and adjusted to 1 \( \times 10^7\) CFU/ml. Blood cells were stimulated with 20 \( \mu l \) of bacteria. Before challenge of neutrophils, bacteria were opsonized with different dilutions of UK-66P antibody (0.3 mg/ml or 0.6 mg/ml) or isotype control antibody (IC; dose equivalent) for 20 min at room temperature. In a forward-side scatter dot plot, the gate was set on granulocytes. The mean fluorescence intensity (MFI) correlating with oxidation quantity per individual neutrophil (oxidative burst) and the percentage of neutrophils (recruitment) having produced reactive oxygen metabolites were analyzed. For that purpose, a negative-control sample was used to set a marker (M1) for fluorescence 1 (FL1) so that less than 1% of the events were positive. In the study samples, the numbers of events above this marker position were counted. Cells were analyzed using a FACS Calibur flow cytometer and CellQuestPro and WinMDI 2.9 software.

**Neutrophil intracellular survival assay.** Neutrophil intracellular survival assays were performed as follows. Bacterial cultures were washed twice in PBS, adjusted to 5 \( \times 10^7\) CFU, mixed with 100 \( \mu l \) whole mouse blood, and then incubated at 37°C in a water shaker. Before coincidence, bacteria were opsonized with UK-66P antibody (0.6 mg/ml) or isotype control antibody (IC; dose equivalent) for 20 min at room temperature. Gentamicin (final concentration, 400 \( \mu g/ml \) ) and lysostaphin (final concentration, 100 \( \mu g/ml \) ) were added after 45 min to kill extracellular bacteria. At 60 min, the contents of samples were withdrawn, centrifuged to pellet the neutrophils, and washed to remove the antibiotic medium. Neutrophils were then lysed in 1% saponin, and CFU were calculated by plating on TSA.

**Catheter-related generalized infection in mice.** The Ethics Committee of the Lower Franconia authorities endorsed all animal studies. Age- and gender-matched NMRI mice (Charles River, Sulzfeld, Germany) were used in the experiment. Mice were intraperitoneally anesthetized with xylazine (8 mg/kg body weight) and ketamine (100 mg/kg body weight), and a central venous catheter was surgically placed as already described (23). Twenty-four hours after surgery, the mice were inoculated via the catheter with 100 \( \mu l \) of an \textit{S. aureus} suspension containing 1 \( \times 10^8\) CFU \textit{S. aureus} bacteria. The bacterial suspension was allowed to dwell within the catheter lumen for 15 min. The content of the catheter was then flushed with 0.2 ml 0.9% saline. Treated mice received intravenously UK-66P (double-dose regimen, i.e., 15 mg/kg in a volume of 100 \( \mu l \) immediately and 24 h after bacterial challenge), and control mice received an isotype control antibody. Body weight and general appearance were assessed daily during the experiment. Five days postinoculation, the mice were euthanized by CO\(_2\) inhalation. Aseptically harvested organs were homogenized in 2 ml saline. Furthermore, the location of the catheter in the superior vena cava was confirmed, the explanted catheter irrigated with 2 ml saline, and the irrigation fluid collected. Serial dilutions of the organ homogenates and catheter fluid collections were cultured on manniott salt phenol red agar plates for at least 48 h at 37°C. The number of bacteria recovered from each organ was plotted versus time postinfection as a Tukey box-and-whisker plot by using GraphPad Prism version 5.00 for Windows (GraphPad Software, San Diego, CA).

**Septis survival model.** Age- and gender-matched NMRI mice (Charles River, Sulzfeld, Germany) were used in the experiment. Animals were challenged on day 0 by intravenous injection with 5 \( \times 10^7\) CFU of \textit{S. aureus} USA300 and MA12 or IsaA mutant \textit{S. aureus} MA12 \( \Delta a:s.a. \). Treated mice received intravenously UK-66P (double-dose regimen, i.e., 15 mg/kg in a volume of 100 \( \mu l \) immediately and 24 h after bacterial challenge), and control mice received an isotype control antibody. Animals were monitored for 8 days, and lethal disease was recorded.

**Statistical analysis.** Statistical analysis between treated and control groups was performed using the nonparametric Mann Whitney test. Bacterial burdens in the organs were additionally analyzed by Kruskal-Wallis one-way analysis of variance by ranks with Dunn’s posttest. The log rank Mantel-Cox test was used to analyze the statistical significance of the survival data. For all comparisons, a \( P \) value of <0.05 was considered statistically significant.
RESULTS

Affinity of anti-IsaA monoclonal antibodies. Biosensor analyses of multiple monoclonal antibodies to IsaA were initiated to characterize the binding profiles. Preliminary ELISAs screened a panel of hybridomas for binding to recombinant IsaA (rIsaA) protein. Antibodies that were ELISA positive were applied for a secondary screen. Biacore studies analyzed positive hybridoma clones for high-affinity interaction with rIsaA. By application of the settings described above, a specific anti-IsaA antibody solution (UK-66P) interacted with the 29-kDa rIsaA antigen with a high affinity and a slow off-rate, indicating a strong and highly specific interaction (Fig. 1). In the experiments with serial antibody dilutions in the range of 0.8 to 400 nM, an equilibrium dissociation constant (Kd) of 1.7 nM was determined. Rate constants for association (ka) and dissociation (kd) of the interaction between UK-66P and rIsaA were determined to be $1.8 \times 10^5$ M$^{-1}$ s$^{-1}$ and $3.1 \times 10^{-4}$ s$^{-1}$, respectively.

Functional characterization of UK-66P. The monoclonal antibody UK-66P was selected for further studies based on its high binding affinity to rIsaA. UK-66P was determined to be of the IgG1 subclass, and indirect immunofluorescence on viable *S. aureus* showed its ability to bind to the cell surface-exposed IsaA antigen. Strain MA12, the isogenic IsaA knockout strain MA12 ΔisaA, and the protein A knockout strain Cowan I Δspa were used for staining. Bacteria were incubated with UK-66P followed by fluorescein isothiocyanate-labeled anti-mouse Ig, and binding of UK-66P to the bacterial surface was visualized by fluorescence microscopy (Fig. 2A to C). Viable cells of *S. aureus* MA12 interacted with the IsaA-specific monoclonal antibody UK-66P, while the IsaA mutant strain did not interact, as demonstrated by lack of fluorescence on these cells. The *S. aureus* protein A knockout strain also bound UK-66P, indicating no cross-reactivity with protein A.

The targeted IsaA antigen is found to be conserved among all sequenced methicillin-sensitive and methicillin-resistant staphylococcal strains. Subsequently, binding of UK-66P to a collection of seven representative isolates, i.e., strain ANS46 (SCCmec III), strain BK2464 (SCCmec II), strain HDE288 (SCCmec IV), strain MU50 (vancomycin-resistant *S. aureus* [VRSA]), strain MW2 (CA-MRSA), strain USA300 (CA-MRSA), and strain EMSRA-15 (epidemic MRSA) was constant, as verified by Western blotting.

UK-66P mediates activation of professional phagocytes. As the monoclonal antibody UK-66P recognizes IsaA on the surface of *S. aureus*, secondary experiments were performed to determine if the antibody UK-66P could also act as an opsonizing agent, resulting in the engulfment of bacteria by activated neutrophils. To quantify phagocytosis, we scored the percentage of oxidizing neutrophils. Neutrophils in whole mouse blood were coincubated with either wild-type *S. aureus* or IsaA mutant *S. aureus* in the presence of UK-66P, isotype control antibody (IC), or saline at 30 and 60 min (Fig. 3A and B). At both time points, the fraction of oxidizing neutrophils in wild-type bacteria was significantly higher after coincubation with UK-66P than after coincubation with the isotype control.
(Mann-Whitney test, $P < 0.05$). More precisely, in the presence of UK-66P (0.6 mg/ml), 46.1% and 97.7% of neutrophils were activated during coincubation periods of 30 and 60 min, respectively (Fig. 3A). The mean percentages of oxidizing neutrophils were 20.9% and 55.2% with the IC after 30- and 60-min incubation times, respectively. In the absence of antibodies (saline), the mean percentages of oxidizing neutrophils were 11.8% and 45.5% after incubation times of 30 min and 60 min, respectively. Specificity controls followed the same experimental setup except for the use of IsaA mutant $S. aureus$ (Fig. 3B). Under these conditions, no UK-66P-dependent increase in the percentage of activated neutrophils was detectable, compared to the results for IC- and saline-primed neutrophils. In the presence of UK-66P (0.6 mg/ml), 8.8% and 56% of neutrophils were activated during coincubation periods of 30 and 60 min, respectively (Fig. 3B). The mean percentages of oxidizing neutrophils were 24.8% and 66.2% with the IC after incubation times of 30 and 60 min, respectively. In the control incubated with saline, the mean percentages of oxidizing neutrophils were 21% and 53% after incubation times of 30 and 60 min, respectively.

**Oxidative burst of neutrophils in response to stimulation with UK-66P.** Since increased UK-66P-dependent neutrophil activation does not necessarily imply enhanced bacterial elimination, we measured the quantity of superoxide production per individual neutrophil during phagocytosis of $S. aureus$ in professional phagocytes. Neutrophils in whole mouse blood were incubated with UK-66P-opsonized wild-type or IsaA mutant $S. aureus$. The production of reactive oxygen metabolites was determined via flow cytometric analysis by measuring the conversion of the fluorogenic substrate DHR123 to fluorescent rhodamine 123 (R123). Oxidative burst induced by wild-type $S. aureus$ in the absence of extrinsic opsonin (saline) was defined as the baseline mean fluorescence intensity (MFI of 331). The results show that the oxidation quantity by wild-type $S. aureus$ in the presence of UK-66P at 0.6 mg/ml was significantly higher than that after costimulation with IC (MFIs of 688 and 366, respectively; Mann-Whitney test, $P = 0.029$) (Fig. 4A and C). Furthermore, the production of superoxide was dose dependent, as half of the UK-66P dose (0.3 mg/ml) did not significantly increase the oxidation quantity compared to that with IC (MFIs of 564 and 366, respectively; Mann-Whitney test, $P = 0.057$) (Fig. 4A and C). The UK-66P-dependent specificity was demonstrated by a failure to produce a significant potentiation of oxidative burst following costimulation with the mutant $S. aureus$ strain lacking IsaA expression. The level of oxidative burst was equal to that for isotype control antibody-opsonized or nonopsonized (saline) mutant bacteria, with MFIs of 284 and 287 for UK-66P at doses of 0.3 and 0.6 mg/ml, respectively, an MFI of 294 for IC, and an MFI of 290 for saline (Fig. 4B and C). Altogether, the oxidative burst activity per neutrophil stimulated with wild-type $S. aureus$ in the presence of adequate UK-66P was approximately 2-fold higher than that for the controls. These results suggest that UK-66P is not only an activator for professional phagocytes but also a stimulus for oxidative burst activity in a dose-dependent fashion.

**Effect of UK-66P on the bactericidal activity of professional phagocytes against $S. aureus$.** Using an *ex vivo* system, we determined if the increased oxidant activity of UK-66P translates to enhanced bacterial killing by an innate immune mechanism. After the addition of either UK-66P- or IC-opsonized wild-type or IsaA mutant $S. aureus$ to 100 $\mu$l whole mouse blood for 30 min, samples were plated to enumerate survivors after neutrophil lysis. The initial inoculum applied consisted of $5 \times 10^7$ bacteria. Opsonization of bacteria with UK-66P significantly enhanced bacterial killing by whole-blood neutrophils compared to that for IC-opsonized bacteria (mean CFU ± standard deviation [SD], $1.13 \times 10^5$ ± 9.38 $\times 10^4$ and $2.99 \times 10^5$ ± 3.65 $\times 10^5$, respectively; Mann-Whitney test, $P = 0.0286$) (Fig. 5). This effect was not explainable by differences in phagocytosis rate, since levels of uptake of wild-type $S. aureus$ were fairly comparable in the presence of either UK-66P or IC (data not shown). Therefore, differences in phagocytic killing were clearly attributable to binding of UK-66P to IsaA, since UK-66P- and IC-treated IsaA mutant $S. aureus$...
produced similar results (mean CFU ± SD, 1.8 × 10^7 ± 1.3 × 10^7 and 1.9 × 10^5 ± 6.1 × 10^3, respectively) (Fig. 5).

**Therapeutic efficacy of UK-66P in a catheter-related sepsis model.** In order to stress the importance of the ex vivo results, we tested the therapeutic efficacy of UK-66P in a sublethal catheter-related sepsis model in mice. Bacterial challenge and treatment were executed 24 h after microsurgical implantation of a catheter into the internal jugular vein of mice. Animals with weight loss greater than 5% after surgery compared to baseline values were excluded from the study to avoid compounding effects of anesthesia or surgical preparation. All elected mice were challenged with 1 × 10^7 CFU *S. aureus* MA12 via the catheter. Mice were then treated via the catheter with UK-66P (7 mice; double-dose regimen, i.e., 15 mg/kg in a volume of 100 μl immediately and 24 h after bacterial challenge to yield an effective dose of 30 mg/kg) or IC (9 mice; dose and volume equivalent). Mice were sacrificed 5 days after *S. aureus* challenge. Numbers of viable bacteria in the liver, lung, heart, spleen, and kidneys following therapy with either UK-66P or IC were quantitated and graphed against time postinfection (Fig. 6). In addition, the catheters were collected and indwelling bacteria obtained. Bacteria from isotype control antibody-treated mice preferentially colonized the kidneys over the infection period. Analysis of the bacterial load in this organ system revealed a significant difference in the numbers of recovered wild-type *S. aureus* bacteria after UK-66P and IC treatment (Kruskal-Wallis test with Dunn’s posttest, P < 0.05), with a greater recovery of bacteria in IC-treated animals. The protective effect of the UK-66P treatment became apparent in the kidneys, resulting in approximately 3 log CFU reduction compared to IC. In contrast, the CFU in lung, liver, heart, and spleen did not differ between UK-66P- and IC-treated mice. The specific infection burden within each organ system is presented in Table 1. In addition, the number of bacteria obtained from the catheters in the IC group was not significantly different from the number of bacteria obtained from catheters in the UK-66P treatment group (mean CFU [range], 2.8 × 10^5 [1.0 × 10^5–3.1 × 10^5] and 1.3 × 10^6 [1.3 × 10^5–2.3 × 10^6], respectively).

**UK-66P treatment protects animals against lethal challenge with *S. aureus***. In order to corroborate the obtained results, a
different experimental model was introduced. Effective immunotherapy for *S. aureus* should protect mice against a lethal challenge of *S. aureus*. Furthermore, immunotherapy must be effective against a wide range of clinically relevant isolates. Therefore, *S. aureus* strain USA300 was additionally included. USA300 is one of the most frequent causes of community-associated infections in the United States (26), and protection against this strain is of crucial importance for immunotherapeutic efforts. To test whether UK-66P immunotherapy protects against lethal-challenge infections, mice were treated intravenously with UK-66P or isotype control antibody. Challenges of $5 \times 10^6$ CFU of wild-type *S. aureus* USA300, wild-type MA12, and the IsaA mutant (MA12 $\Delta$isaA) were administered intravenously, and mice were monitored for 8 days. Isotype control antibody treatment in wild-type *S. aureus* USA300 and MA12 had no effect, with 57% and 75% mortality rates, respectively, over the study period (Fig. 7). In contrast, UK-66P treatment protected against lethal-challenge infections and challenged with *S. aureus* USA300 (0% mortality rate; log rank Mantel-Cox test, $P = 0.038$) and *S. aureus* MA12 (25% mortality rate; log rank Mantel-Cox test, $P = 0.041$). Clearly, the immunotherapeutic potential of UK-66P was demonstrated by the fact that mice challenged with *S. aureus* MA12 $\Delta$isaA were not protected by anti-IsaA antibodies, compared to results for isotype control antibody-treated mice (50 and 38% mortality rates, respectively; log rank Mantel-Cox test, $P = 0.55$). These results suggest that passive immunotherapy with UK-66P monoclonal antibody can generate increased protection against lethal challenge.

**DISCUSSION**

*S. aureus* causes a wide variety of diseases, ranging from superficial skin lesions to life-threatening invasive infections, and those at high risk include individuals with short-term or permanent states of immunosuppression, such as patients undergoing surgery, cancer patients, intensive care unit (ICU) patients, and patients with dialysis dependence, diabetes, or HIV (28, 30). There is still a high mortality rate associated with severe *S. aureus* infections, especially those caused by multiple-antibiotic-resistant strains. Therefore, active or passive immunotherapy has been regarded as a promising adjunctive treatment approach that can bolster the immune response and circumvent rising rates of antimicrobial drug resistance. Experimental evidence strongly supports the concept, but successful clinical trials are still pending (35).

In the present report, the therapeutic efficacy of the mouse monoclonal antibody UK-66P, binding the immunodominant antigen IsaA, has been evaluated *in vivo*. The UK-66P hyper-immune preparation, passively applied in two different experimental mouse models, significantly lowered *S. aureus* burden in kidneys and protected mice against lethal challenge. The kidneys are the predominant infection site in mice after intravenous challenge with *S. aureus* (32, 39). Lowering the bacterial load in this single organ system limits the establishment of infectious foci and thereby curbs the severity of staphylococcal infections. The specific IgG1 subclass preparation was chosen for the experimental studies, as the secondary IgG1 immune response seems to be crucial in *S. aureus* infections (16, 29). High-affinity binding kinetics of antibodies was demonstrated by Biacore analysis.

Further investigation was conducted to clarify the UK-66P antibody mode of action. Obviously, UK-66P has no direct blocking function to IsaA. Instead, binding of UK-66P to IsaA on the cell surface triggers phagocytosis and subsequent intracellular killing of *S. aureus*. The bactericidal activity of neutrophils after UK-66P treatment correlates with augmentation in the respiratory burst of these cells. The observation of neutrophil killing upon exposure to high concentrations of superoxide and hydrogen peroxide is concordant with other studies (13). Likewise, mice lacking NADPH oxidase activity inefficiently clear *S. aureus* infections (33). The *ex vivo* results of the antibody-mediated phagocytosis transferred to the catheter-related infection and sepsis model may explain the effective reduction of *S. aureus* bacteria in the treated hosts, with

$^a$, significant difference by Kruskal-Wallis test with Dunn's posttest; NS, not significant.
improved survival. Phagocytosis and intracellular killing of *S. aureus* decrease the initial bacterial proportion, helping to displace the infective balance toward the host organism (1). In addition, the percentage of surviving *S. aureus* bacteria inside various cells, including phagocytes, contributes to the pathogenesis of staphylococcal infections (11). In our ex vivo studies, the UK-66P immunotherapy reduced the number of viable *S. aureus* bacteria within phagocytes by one-third compared with the results for the control. In this context, a recent study examined the comparative lethality of clinical *S. aureus* isolates in a mouse septic model, and lowering the infectious dose of viable bacteria by approximately one-third led to a marked decrease in mortality within a given time (40).

Originally, IsaA was identified in a screening approach for immunodominant antigens that may serve as vaccine candidates or targets for passive immunotherapy (24). The surface-associated IsaA antigen is found to be conserved among all sequenced staphylococcal strains, including community-associated methicillin-resistant *S. aureus* strains, such as USA300 (41). Moreover, we demonstrated binding of UK-66P to IsaA of major clinical *S. aureus* lineages. In vivo data suggest that antibody reactivity raised to IsaA tends to be a ubiquitous mechanism in host immune defense against invasive *S. aureus* infections (9, 24). Importantly, reactive IgG titers against IsaA are significantly increased in serum samples obtained from individuals with confirmed disease compared to those from healthy individuals. Furthermore, comparison of IgG titers against IsaA from healthy noncarriers and carriers showed that there are significantly increased reactive titers in the latter group (6). We hypothesize that the amount of anti-IsaA-specific antibody represents one important component that modulates the outcome of human systemic *S. aureus* infection. Nevertheless, the significance of the antibody response to IsaA in a human infection has not yet been defined conclusively.

Selection of a protective target antigen is the key factor in the development of an effective vaccine or passive immunization strategy. Traditionally, virulence-associated factors have been regarded as promising vaccine candidates due to their potential role in pathogenesis. This concept is especially questionable for *S. aureus*, since the pathogen expresses a broad range of toxins and adhesins that are important in different phases of disease but are not solely essential for virulence, as others may compensate for a loss of function, e.g., by blocking antibodies. Alternatively, naturally raised antibodies in humans exposed to staphylococcal invasive infections may select antigens as potential targets for immunotherapy (6, 24, 27, 46). However, as native protective immunity to staphylococcal infections does not exist to a significant degree and individuals with colonization of invasive infections elicit a unique immune response to different *S. aureus* proteins, selection of a universal protective antigen is highly challenging (14, 42). Moreover, certain patients develop recurrent infections, with the same strain in up to 35% of cases, despite a broad spectrum of existing antistaphylococcal antibodies (15). On the other hand, those patients that become infected with their own strain have a significantly greater chance to survive invasive *S. aureus* infections (45).

Although our approach has been demonstrated to be effective in two animal model systems, clinical trials are still lacking. Very recently, we have identified the antigen binding region of UK-66P and grafted the mouse complementarity-determining regions into human variable regions that were joined to human constant regions (unpublished data). Studies on binding and functional activity of the humanized antibody are in progress. However, some important issues remain to be addressed before this antibody can proceed to clinical trials. For example, the optimal treatment regimen has to be determined, as does the general accessibility of IsaA in all strains, including those of different capsule types.

Together, the results presented in this study have demonstrated that the immunotherapy strategy focusing on IsaA, targeting only a single epitope of *S. aureus*, is effective in reducing bacteria in experimental infections, due to enhanced opsonophagocytosis with effective intracellular killing. Based on the mechanism of action, the ability of therapeutic antibodies to work cooperatively with the immune system in this way has important implications for the selection of IsaA as a target for immunotherapy of staphylococcal infections. Further analysis of the humanized antibody will help to establish the suitability of this immunotherapy.
