Helicobacter pylori is a globally important and genetically diverse gastric pathogen that infects most people in developing countries. Eradication efforts are complicated by antibiotic resistance, which varies in frequency geographically. There are very few data on resistance in African strains. Sixty-four Gambian H. pylori strains were tested for antibiotic susceptibility. The role of rdxA in metronidazole (Mtz) susceptibility was tested by DNA transformation and sequencing; RdxA protein variants were interpreted in terms of RdxA structure. Forty-four strains (69%) were resistant to at least 8 µg of Mtz/ml. All six strains from infants, but only 24% of strains from adults, were sensitive (P = 0.0031). Representative Mtz-resistant (Mtzr) strains were rendered Mtz susceptible (Mtzs) by transformation with a functional rdxA gene; conversely, Mtzs strains were rendered Mtzr by rdxA inactivation. Many mutations were found by Gambian H. pylori rdxA sequencing; mutations that probably inactivated rdxA in Mtzs strains were identified and explained using RdxA protein’s structure. All of the strains were sensitive to clarithromycin and erythromycin. Amoxicillin and tetracycline resistance was rare. Sequence analysis indicated that most tetracycline resistance, when found, was not due to 16S rRNA gene mutations. These data suggest caution in the use of Mtz-based therapies in The Gambia. The increasing use of macrolides against respiratory infections in The Gambia calls for continued antibiotic susceptibility monitoring. The rich variety of rdxA mutations that we found will be useful in further structure-function studies of RdxA, the enzyme responsible for Mtz susceptibility in this important pathogen.

H. pylori chronically infects most people in developing countries (1, 2), typically starting in infancy (2–4) and lasting for life. It also remains a significant pathogen in industrialized countries, infecting some 10 to 40% of adults in many societies. Chronic H. pylori infection is a major cause of gastric (stomach) and duodenal ulcers and gastric cancer (5–7). It also increases the risk of infection by other gastrointestinal pathogens, iron deficiency anemia, and infant malnutrition and growth faltering, especially among the very poor (8, 9). These latter conditions are of particular concern in The Gambia, a small developing country on the West Coast of Africa. Fortunately, many H. pylori-associated illnesses can be prevented or cured by the timely eradication of the bacterium, which typically involves a 1 to 2 weeks of treatment with metronidazole (Mtz), amoxicillin (Amo), or clarithromycin (Cla), when affordable, and/or tetracycline (Tet), in combination with a proton pump inhibitor such as omeprazole, and/or bismuth, where allowed by local regulations (10). H. pylori transmission tends to be highly localized and preferentially intrahousehold (11, 12) in industrialized societies and often also between households in the local community in developing country settings (13). Given the relatively localized transmission, successful eradication from many members of a household or community might markedly diminish the risk of new infections, especially of newborns, and thereby contribute importantly to public health.

Resistance to useful antimicrobials, especially Mtz and Cla, has been a major problem in some societies, even among people not previously treated for their H. pylori infections. Such resistance is generally attributable to inadvertent H. pylori exposure during treatment for other conditions (14). Mtz itself is an innocuous prodrug that is activated by chemical reduction to hydroxylamine type compounds, which are bactericidal to H. pylori (15). In the strains studied to date, mostly from industrialized societies, a modest level of Mtz resistance (e.g., to 8 or 16 µg of Mtz/ml) was usually associated with inactivation of the gene rdxA, which encodes a nonessential oxygen-insensitive NAPDH nitroreductase that chemically reduces Mtz in vitro (16). Higher-level resistance in rdxA mutant strains, e.g., to 32 µg of Mtz/ml, resulted from the inactivation of frxA, a related but generally less strongly transcribed nitroreductase gene; however, higher-level resistance can result from mutations in any of several additional genes that likely also affect intracellular redox potential (16–18). The hydroxylamine-type derivatives of Mtz that RdxA protein generates are mutagenic, such that exposure to sublethal Mtz concentrations (15) induces as well as selects for mutations to Mtz resistance.

No commonly used anti-H. pylori drugs other than Mtz are known to require activation to render them bactericidal, nor to be so highly mutagenic. In addition, the several resistances to these
other drugs identified to date involve specific mutational changes that alter the target’s function. In particular, resistance to the related macrolides erythromycin (Ery) and clarithromycin (Cla), which are used in anti-\textit{H. pylori} therapy, is usually achieved by point mutations at either of two adjacent sites in 23S rRNA (19, 20) that diminish macrolide binding to the ribosome. Cla resistance seems to be rare in many societies but common (more than one-fourth of strains) in others (21, 22). The observed prevalence probably reflects a combination of the very few rRNA sites in which sequence changes can confer resistance and are not too deleterious for the bacterium, a need to incorporate any resistance mutation in both 23S rRNA genes to achieve a resistance phenotype, and the intensity of macrolide use for other infections and thereby inadvertent exposure of resident \textit{H. pylori} strains.

Tet resistance is much rarer than Mtz or Cla resistance (23, 24), although several bona fide resistant strains have been identified and analyzed. In the best-described case, modest resistance resulted from three contiguous changes in the Tet binding pocket in 16S rRNA (positions 965 to 967) (23, 25). Lower-level resistance was achieved by mutation at one or two of these positions and/or by mutations in genes in other chromosomal locations that have not yet been identified but are suspected to affect bacterial permeability or efflux (23). Amo resistance is also very rare, but where it is found it has been ascribed to mutation in a penicillin-binding protein involved in cell wall metabolism (26–30).

The present study of drug susceptibility and resistance in Gambian \textit{H. pylori} strains was motivated in part by considering that \textit{H. pylori} is a genetically very diverse species, with different genotypes predominating in different well-separated geographic regions, even in different parts of Africa (31) and that most studies of drug susceptibility and resistance have focused on strains from Europe, the Americas, or Asia. As with many infection-related topics, there have been far fewer critical studies of antimicrobial resistance and susceptibility of \textit{H. pylori} strains from Africa, especially those from West Africa—the ancestral home of most people of African ethnicity in the Americas. Given \textit{H. pylori} transmission preferentially within families and local communities (11–13), West African strains may well have contributed to \textit{H. pylori} gene pools in the Americas.

Bearing in mind \textit{H. pylori}’s impact on public health worldwide, The Gambia included, and the distinctiveness of African strains, we assessed here the frequencies of resistance to Amo, Cla, Ery, Mtz, and Tet in a set of 64 strains from Gambian citizens. We tested the importance of \textit{rdxA} status for Mtz susceptibility and resistance by transformation and DNA sequence analysis, and interpreted amino acid sequence differences in RdxA protein in terms of its recently determined structure (32). We also tested by DNA sequencing whether 16S rRNA gene mutations could be responsible for the very few Tet-resistant (Tet’) isolates found as minority components of mixed \textit{H. pylori} populations from several patient biopsy specimens.

**MATERIALS AND METHODS**

**Patients.** Sixty-four patients were enrolled in the present study: 35 male and 29 female, ranging from 18 months to 70 years, with a mean age of 30 years. These patients were part of a group recruited during a primary study of \textit{H. pylori} genetic diversity reported previously (33). All subjects were Gambian citizens and provided written informed consent. Children younger than 18 years were enrolled only after parental/guardian written informed consent. The study was approved by the Gambia Government/MRC joint ethics committee and the international Review Board of the U.S. National Institute of Health Division of Microbiology Infectious Diseases.

**Bacterial cultures.** \textit{H. pylori} strains were cultured, generally as pools of bacteria, from gastric biopsy samples on brain heart infusion (BHI) agar (Difco, USA) supplemented with 7% horse blood, 0.4% IsoViteX, trimethoprim at 5 \(\mu\)g/ml, vancomycin at 6 \(\mu\)g/ml, and amphotericin at 8 \(\mu\)g/ml. The plates were incubated at 37°C in a microaerobic atmosphere for 3 days as previously described (33). Exponential growth of these strains was obtained by culturing on fresh BHI agar medium for 24 h. Strains were stored at −70°C as suspensions of fresh exponentially growing cells suspended in BHI broth with 20% glycerol.

**MIC determined by agar dilution.** freshly grown bacteria were screened for antibiotic resistance by suspending them in phosphate-buffered saline (pH 7.2) (Inovitrogen, USA) at a 10³ McFarland standard. A series of sequential 10-fold dilutions was prepared from this suspension, and 10 \(\mu\)l of each dilution was spot inoculated onto BHI medium containing antibiotics appropriate for this experiment as follows: Amo (2 \(\mu\)g/ml), Cla (2 \(\mu\)g/ml), Ery (2 \(\mu\)g/ml), Tet (2 \(\mu\)g/ml), and Mtz (8 \(\mu\)g/ml). When resistance was encountered, susceptibility to higher concentrations of the antibiotic was tested. The plates were incubated at 37°C under microaerobic conditions for 5 days. A strain was considered to be susceptible to a concentration of an antibiotic that caused at least a 10-fold decrease in the efficiency of colony formation by individual cells (efficiency of plating [EOP]) as previously described (16, 21, 23, 34).

**DNA extraction.** Total genomic DNA was extracted using a commercial kit (rDNA minikit; Qiagen, United Kingdom) according to the manufacturer’s guidelines and stored at −20°C.

**RAPD-PCR.** RAPD (randomly) amplified polymorphic DNA typing was carried out using two arbitrary primers (1254 [5’-CGGACGCCAC-3’] and 1283 [5’-GGGATCCCCA-3’]) as previously described (35). The cycling parameters were 45 cycles of 94°C for 1 min, 36°C for 1 min, and 72°C for 2 min. The amplified products were detected by electrophoresis on a 1.5% (vol/vol) agarose gel with ethidium bromide (500 ng/ml), and the bands were visualized by using Gel Doc 2000 (Bio-Rad Laboratories, Milan, Italy).

16S rRNA gene and \textit{rdxA} gene sequencing. To detect changes in 16S rRNA sequences associated with Tet resistance, 16S rRNA genes were amplified by PCR with the primers 16S-F (5’-GGTTCCTGATAGGATTTAATGTGATGCA-3’) and 16S-R (5’-TATGGGAGTTTATCCTGCTCTG-3’), and the amplified 16S rRNA genes were sequenced as previously described (23). To detect mutations associated with Mtz resistance, \textit{rdxA} genes of 51 strains (33 Mtz’ and 18 Mtz”) were amplified by PCR with the primers rdxAF (5’-GTTGTGTTAGGATTATACGG-3’) and rdxAR (5’-CACCCTTAAAAGGAGGTATGAACCC-3’), the PCR products were sequenced, and the sequences were edited, aligned, and analyzed by using the DNASTar program (version 7; Lasergene, USA) and the Clustalw2 program.

**Mutant RdxA protein structure analysis.** The impact on protein structure of mutations found in \textit{rdxA} genes from Mtz’ and Mtz” \textit{H pylori} strains was assessed by modeling the mutations in the X-ray structure of the RdxA enzyme (PDB ID 3QDL) (32) using Swiss-PdbViewer (36). Distances from mutated residues to flavin mononucleotide (FMN) atoms or to the closest atoms of the associated monomer of the RdxA dimer were also calculated using Swiss-PdbViewer. Solvent exposure of mutated residues was calculated using the ProtSA server (37). Proteins encoded by genes with insertion, deletion, or nonsense (stop) codon mutations were not modeled. Individual point mutations at the protein surface and far from the FMN group and dimer interface were considered to be neutral and did not affect RdxA function. Mutations resulting in small to large residue replacement at the protein core or leading to the loss of hydrogen bonds between apoprotein and FMN, the burial of polar or charged residues, or the replacement of Gly residues exhibiting dihedral angles not allowed to other residues were regarded as structurally disruptive and thus potentially causing the loss of RdxA function.

Statistical analysis. Comparisons of antimicrobial resistance in strains from children versus adults, males versus females, and the distribution of *rdxA* nonsense mutations in different groups of strains were determined using the Fisher exact test; a *P* value of <0.05 was considered significant.

RESULTS

Of the 64 strains tested for Mtz susceptibility, 20 (31.2%) were sensitive (single cells unable to form colonies) on medium with Mtz at 8 µg/ml, and 44 (68.8%) were resistant. All six strains from infants (18 to 31 months old) were sensitive to this modest level of Mtz, whereas only 14 (24%) of 58 strains from adults were sensitive (*P* = 0.0031; Table 1). The prevalence of Mtz resistance in males versus females was 66% versus 72%, respectively (*P* > 0.05; Table 1 and Fig. 1).

All but 3 of the 44 strains that were resistant to 8 µg of Mtz/ml also grew well on medium with 16 µg of Mtz/ml. In addition, 28 of these strains also grew on medium with 32 µg of Mtz/ml; and 2 of the 28 grew on medium with 64 µg of Mtz/ml. None of our 44 strains grew on medium with 128 µg of Mtz/ml (Fig. 2).

In further tests of strains that did not grow with 8 µg of Mtz/ml, 2 of the 6 representative strains from infants (18 to 31 months old), and 2 of 14 representative strains from adults grew on medium with only 4 µg of Mtz/ml.

*rdxA* (nitroreductase) gene analysis. A transformation test was used to determine whether Mtz$^+$ strains were distinct metabolically from most susceptible reference strains in requiring more than just *rdxA* inactivation to achieve Mtz resistance (16–18). Eleven Mtz$^+$ strains were transformed with genomic DNA from a derivative of strain 26695 whose *rdxA* gene had been replaced with a chloramphenicol-resistant (*Cam*) cassette (Δ*rdxA-cat*). Each of the 10 to 20 *Cam*$^+$ transformant colonies tested from each of the 11 strain transformations grew well on agar with 8 µg of Mtz/ml. This outcome indicates that most or all Mtz$^+$ Gambian *H. pylori* strains are just one mutational (*rdxA* inactivation) step away from becoming resistant. In a converse experiment, we tested whether mutation in *rdxA* was important for the resistance of Mtz$^+$ Gambian strains. This entailed transforming 12 representative Mtz$^-$ strains with genomic DNA from an *H. pylori* strain containing a kanamycin-resistant (*Kan*) cassette inserted next to a functional *rdxA* gene. We expected that a fraction of *Kan*$^+$ transformants would acquire the donor strain’s *rdxA*$^{-}$ (functional) allele (38), even though most might retain the recipient *rdxA* mutant allele because *H. pylori* transformation tends to involve mostly short DNA fragments (39). At least 2 of the 20 to 30 *Kan*$^+$ transformants scored from each of 12 Mtz$^-$ recipient strains were found to be Mtz$^-$ on agar with 8 µg of Mtz/ml, even though most *Kan*$^+$ transformants remained Mtz$^+$. We infer that these few *Kan*$^+$ Mtz$^-$ transformants had gained the donor’s functional *rdxA* allele and thereby conclude that *rdxA* inactivation is needed for most or all Mtz$^+$ Gambian *H. pylori* strains if they are to become Mtz$^-$.

Sequence comparison of *rdxA* from Mtz$^+$ and Mtz$^-$ strains. The *rdxA* gene was PCR amplified and sequenced from 33 Mtz$^+$ (MIC range, 8 to 32 µg/ml) and 18 Mtz$^-$ Gambian strains (MIC < 8 µg/ml). The average *rdxA* sequence diversities were 3.6% in Mtz$^+$ strains and 3.4% in Mtz$^-$ strains (3.5% overall), which is within the range of diversities among Gambian strain housekeeping genes (range, 1.2 to 4.6%; mean, 2.9%), and whose protein products also act internally in these Gambian strains (O. Secka, unpublished data).

Of the 33 Mtz$^-$ strains characterized, 15 (45.5%) contained nonsense (translation stop) codons within the *rdxA* orf, including 13 of the 19 resistant to 32 µg of Mtz/ml; in contrast, only 2 of the 14 isolates with lower-level resistance (8 to 16 µg/ml) contained nonsense mutations in *rdxA* (*P* = 0.004, Table 2). This difference in distribution is in accord with nonsense mutations causing protein truncation and thus a complete loss of RdxA function. Some missense mutations diminish but do not entirely eliminate an en-
The basis of Mtz resistance in two strains (127R and 104R, which contains R16H, that should decrease FMN binding affinity was also found in an Mtzs strain. However, all of the differences present in strains 127R and 104R were resistant is not obvious: possibly their particular combinations of changes in RdxA diminished function (conferred resistance), or these strains might have polar mutations in the upstream DNA that we did not sequence. Among the 18 rdxA sequences from Mtz r strains, 3 (17%) had internal stop codons (Table 2), and 3 others had point mutations that also might lead to rdxA inactivation, R16H (in one strain) because it should decrease RdxA affinity for FMN’s negatively charged phosphate and A67V (in two strains) because it entails replacement of small alanine by bulky valine in the protein core, although direct tests are needed to learn how severely this replacement affects protein stability and function. If these mutations do indeed cause rdxA inactivation, the Mtz r phenotypes might stem from high-level frxA expression (16, 18); the possibility of nonsense suppressor mutant tRNAs in certain strains also merits consideration. The nonsense mutations between Mtzs and Mtz r strains was not significant (P = 0.0025, Table 2); however, overall, the nonsense mutations between Mtz r and Mtz s strains was not (P = 0.065, Table 2).

Fifteen substitutions were found only in Mtz s isolates (H25R, S43L, P44L, A80I, A80T, C87Y, G170S, G189C, E194K, D205A, and A206T) in 104R were also present in many other resistant and susceptible strains and thus may not perturb function. We interpret that most of these differences simply reflect neutral mutations in accord with H. pylori’s great genetic diversity. None of the three mutations that were specific to 104R (E133K, G170S, and E194K) is expected to affect RdxA function because they appeared on the protein surface far from the FMN binding site. Thus, why strains 127R and 104R were resistant is not obvious: possibly their particular combinations of changes in RdxA diminished function (conferred resistance), or these strains might have polar mutations in the upstream DNA that we did not sequence.

<sup>a</sup> –, strains sensitive at 2 µg/ml were not tested at higher concentrations (8 to 128 µg/ml).

Q197R) and thus might be neutral (of these five, only A67V is suspected of decreasing RdxA function, as noted above).

**Susceptibility of Gambian strains to other antibiotics.** All 64 of our Gambian H. pylori cultures grown directly from gastric biopsy specimens were found to be highly sensitive to the closely related macrolides Cla and Ery. All cultures were also Tet<sup>+</sup> and Amo<sup>+</sup> (Table 3), although one and four of them contained rare Amo<sup>+</sup> and Tet<sup>+</sup> cells able to grow on medium with 2 µg of Amo or Tet/ml, respectively (frequencies of 10^<sup>-3</sup> to 10^<sup>-4</sup>). Further tests of one Tet<sup>+</sup> colony from each of these unusual Tet<sup>+</sup> subclones containing cultures showed that their MICs ranged from 2 to 4 µg of Tet/ml and that each was indistinguishable by RAPD-DNA fingerprinting from the predominant Tet<sup>+</sup> strains from the same biopsy specimen (data not shown). These four sets of strains were not closely related to one another, as expected, since they came from different persons. We found that the PCR-amplified 16S rRNA gene of each Tet<sup>+</sup> strain was identical in sequence to that of its Tet<sup>+</sup> sibling from the same biopsy specimen. We conclude that in each of these four cases, Tet resistance is due to mutation in a gene distinct from that for 16S rRNA.

**DISCUSSION**

H. pylori infection contributes importantly to several human diseases in both developing and industrialized countries and directly impacts on health care systems worldwide. Its public health impact is of particular concern in developing countries because the prevalence of infection is so very high (1, 2).

Here, we scored susceptibility and resistance to clinically relevant anti-H. pylori agents using a test of efficiency of colony formation by single cells. This test is especially useful for scoring susceptibility to Mtz because Mtz can be both mutagenic and bactericidal; it both induces and selects for resistance mutations (15, 16, 18). We found that more than two-thirds of Gambian H. pylori strains were Mtz<sup>+</sup>. This high prevalence can be explained by the relative low cost and easy availability of Mtz in The Gambia, as is typical of developing countries worldwide. Our results are in accord with other reports of many Mtz<sup>+</sup> strains elsewhere in Africa (Senegal, Nigeria, South Africa Cameroon, and Egypt) (40–44), India, and Latin America (45, 46). Typically, somewhat less than half of H. pylori strains from Europe and North America have been found to be Mtz<sup>+</sup> (22), likely reflecting the tighter control of Mtz usage in industrialized than in developing countries. Our observation that all six strains from infants (18 to 31 months of age) were sensitive to 8 µg of Mtz/ml, in contrast to 24% of those from older people ( ≥14 years) (P = 0.005), also merits further examination, especially in light of the possibility that rdxA function might contribute to fitness during the establishment of infection.

Prior studies with other sets of strains had shown that Mtz resistance typically involves inactivation of rdxA, which encodes a nitroreductase that converts Mtz from prodrug to bactericidal agent by chemical reduction. However, H. pylori strains also contain a related gene, frxA, which also confers Mtz susceptibility if highly expressed, independent of rdxA status (16, 43). Our DNA transformation studies indicated that each of 11 Mtz<sup>+</sup> Gambia strains tested required only rdxA inactivation to gain a Mtz<sup>+</sup> phenotype and, conversely, that resistance involved rdxA inactivation in each of the 12 Mtz<sup>+</sup> strains tested.

Sequence analysis of rdxA genes from our strains identified loss-of-function mutations that should cause Mtz resistance similar to those found in previous studies (16, 18, 47). In particular, rdxA nonsense (stop codon) mutations were more common in strains with moderate level resistance (32 µg/ml) than in strains with lower-level resistance (8 to 16 µg/ml), in agreement with other findings (16, 18, 47). However, 3 of 18 Mtz<sup>+</sup> strains had rdxA-null nonsense mutations, and 3 others had point mutations that also possibly might result in inactive RdxA proteins. These observations are consistent with other reports (16, 18, 48, 49) that rdxA inactivation need not always lead to Mtz resistance and can be explained by postulating higher-level expression of the related frxA nitroreductase gene (16, 18).

We also found that most Mtz<sup>+</sup> strains had mutations scattered across the rdxA gene that are not likely to contribute to their resistant phenotype. This is in accord with H. pylori’s well-known great sequence diversity, seen here in the rdxA gene.

Increasingly frequent Cla resistance, up to one-fourth or more of H. pylori strains, has been reported in Europe and North America (21, 22). High prevalence, where encountered, has been attributed to use of macrolides to treat respiratory infections (22, 50–52). In The Gambia, Ery is now routinely used to treat lower respiratory tract and skin infections. However, we found no resistance to Cla or Ery in the 64 H. pylori isolates we tested.

Tet and Amo are also much used. Tet, especially, is inexpensive and readily available in local drug stores in The Gambia, often without prescription. However, its easy availability did not result in much resistance in Gambian H. pylori strains: Tet<sup>+</sup> strains were recovered from pooled cultures from only four patients and then only as very rare cells in the population. This outcome is in accord with the rarity of Tet resistance in H. pylori from other parts of the world (22, 53). None of our four Tet<sup>+</sup> strains had mutational changes in the several allowed positions in the 16S rRNA Tet binding pocket that can result in modest Tet resistance (23, 25). Thus, by default, their resistances are likely to stem from mutations in other loci—a class of mutations previously interpreted as more easily achieved but also likely to diminish H. pylori fitness (23). We propose that the low probability of mutation at just a few specific rRNA sites and the low fitness conferred by Tet resistance mutations in other genes explains the rarity of Tet<sup>+</sup> H. pylori, despite considerable exposure, in The Gambia. Resistance to Amo was also very rare in Gambian strains, much as has been reported for other geographic regions (22, 53).

**Conclusion.** The increased prevalence of resistance to antibiotics used against H. pylori is of great concern, especially in developing countries where the costs of even the least expensive first line drugs are a burden to average citizens. This contributes to the urgency of monitoring antibiotic resistant strain frequencies to...

help clinicians effectively manage patients and their antibiotic regimens and to effectively deal with treatment failure. The rich repertoire of rdxA mutations found in our many Gambian H. pylori strains should be useful for future studies of RdxA structure and function, of how RdxA and its FrxA homolog make H. pylori susceptible to produgs such as Met, and of the roles of these two nitroreductase enzymes in H. pylori’s central metabolic networks.

ACKNOWLEDGMENTS
This study was supported from funds by the Medical Research Council Unit (Fajara, The Gambia) and U.S National Institutes of Health grants RO3-AI061308, R21-AI078237, and R21-AI088337, as well as by fund BFU2010-16297 (Ministerio de Ciencia e Innovación, Spain) and Grupo Protein Target B89 (Diputación General de Aragón, Spain). J.J.G. was funded by the Banco Santander Central Hispano, the Fundación Carolina, and the Universidad de Zaragoza.

We thank the members of the endoscope team of the Clinical Services and Microbiology Department, Medical Research Council Unit, Fajara, The Gambia, and all of the patients and parents who made this study possible.
