ABSTRACT

The rapid increase in the prevalence of antibiotic-resistant pathogens is a global problem that has challenged our ability to treat serious infections. Currently, clinical decisions on treatment are often based on in vitro susceptibility data. The role of the immune system in combating bacterial infections is unequivocal, but it is not well captured quantitatively. In this study, the impact of neutrophils on bacterial clearance was quantitatively assessed in a murine pneumonia model. In vitro time-growth studies were performed to determine the growth rate constants of *Acinetobacter baumannii* ATCC BAA 747 and *Pseudomonas aeruginosa* PAO1. The absolute neutrophil count in mice resulting from different cyclophosphamide preparatory regimens was determined. The dynamic change of bacterial (BAA 747) burden in mice with graded immunosuppression over 24 h was captured by a mathematical model. The fit to the data was satisfactory ($r^2=0.945$). The best-fit maximal kill rate of the bacterial population by neutrophils was $1.743 \text{ h}^{-1}$, the number of neutrophils necessary for 50% maximal killing was $190.8/\text{mm}^3$, and the maximal population size was $1.8 \times 10^9 \text{ CFU/g}$, respectively. Using these model parameter estimates, the model predictions were subsequently validated by the bacterial burden change of PAO1 at 24 h. A simple mathematical model was proposed to quantify the contribution of neutrophils to bacterial clearance and predict the bacterial growth / suppression in animals. Our results provided a novel framework to link in vitro and in vivo information, and may be used to improve clinical treatment of bacterial infections.
The rapid increase in the prevalence of antibiotic-resistant pathogens is a global problem that has challenged our ability to treat serious infections. To prevent further spread of multidrug resistance and returning to the pre-antibiotic era, it is imperative that the current approach to treatment is improved. Presently, clinical decisions on treatment are often based on in vitro susceptibility data (MIC), which only provides information about anti-bacterial activity at a single time point and potentially missing information on the change in bacterial population dynamics over time. Drug selections solely based on MIC values may not always correlate to patient outcomes (11). One major reason for the discrepancy may be due to in vitro investigations neglecting the presence of immune system in patients, which is well known to be significant.

The immune system (especially neutrophils) plays an important role in combating bacterial infections. This is best exemplified by patients with neutropenia or after transplantation, who have a significantly higher mortality than patients without neutropenia (9, 10, 13). However, the effect of the immune system is not well accounted for when data obtained from in vitro investigations are used to provide guidance for treatment. The overall antimicrobial effect in a patient is the sum of the anti-bacterial activity from drug therapy and the effect from the immune system. The functional contribution from the latter is often overlooked and the quantitative contribution of the neutrophils to bacterial clearance is not well established.

*Acinetobacter baumannii* and *Pseudomonas aeruginosa* are important Gram-negative pathogens associated with serious nosocomial infections (5, 12). Multidrug resistance in both species has been increasing over the past decades and correlates with significant morbidity and mortality (3, 6). They have been implicated in numerous global outbreaks and pose
serious challenges to clinicians (4, 7, 14). In this study, we investigated the impact of neutrophils on the clearance of *A. baumannii* in an animal infection model. A simple mathematical model was developed to characterize bacterial behavior over time under a variable degree of immunosuppression. Model predictions of bacterial behavior were subsequently validated using another important pathogen - *P. aeruginosa*. Our quantitative results may provide useful information to improve clinical treatment of bacterial infections.

**MATERIALS AND METHODS**

**Microorganisms.** A wild-type strain of *A. baumannii* ATCC BAA 747 (American Type Culture Collection, Rockville, MD) and a laboratory strain of *P. aeruginosa* PAO1 were used in the study. The bacteria were stored at –70°C in Protect® (Key Scientific Products, Round Rock, TX) storage vials. Fresh isolates were subcultured twice on 5% blood agar plates (Hardy Diagnostics, Santa Maria, CA) for 24 h at 35°C prior to each experiment.

**In vitro time-growth studies.** The in vitro growth rates of AB BAA 747 and PAO1 were determined in cation-adjusted Mueller-Hinton broth (Ca-MHB) (BBL, Sparks, MD). Briefly, 1-2 medium-sized fresh colonies were inoculated in Ca-MHB until reaching log-phase growth. The bacterial suspension was then diluted based on absorbance at 630 nm and transferred to a 50 ml flask containing 20 ml of Ca-MHB. To be consistent with subsequent animal experiments, the baseline inocula of AB BAA 747 and PAO1 used were approximately $1 \times 10^7$ and $1 \times 10^3$ CFU/ml, respectively. The experiments were conducted for 24 h in a shaker water bath at 35 °C. Serial samples (baseline, 1, 2, 3, 4, 6, 8 and 24 h) were obtained in triplicate, and bacterial burden was determined by quantitative culture on Mueller-Hinton Agar (MHA) plates (BBL) after 10× serial dilutions. Colony counts were enumerated after incubation at 35 °C in a humidified incubator for 24 h. The theoretical lower
limit of detection was 100 CFU/ml.

**Modeling of in vitro growth.** The exponential growth of bacterial population over 24 h was analyzed using a mathematical model (18). Details of the model are shown in Figure 1. Based on the best-fit model, the bacterial growth rate constants ($K_g$) were determined by the ADAPT II program (1).

**Animals.** Female Swiss-Webster mice weighing 21-25 g were used (Harlan Laboratories, Indianapolis, IN). The animals were housed in ventilated micro-isolator cages to decrease the risk of infection from extraneous pathogens. The mice were allowed to eat and drink ad libitum. The experimental protocol was approved by the Institutional Animal Care and Use Committee of the University of Houston.

**Determination of absolute neutrophil count (ANC).** A total of 16 mice were randomized divided into 4 groups. One group was used for baseline ANC determination and the other 3 groups were given different cyclophosphamide preparatory regimens to produce a graded immunosuppression in the animals. Each cyclophosphamide regimen contained two doses administered intraperitoneally; the first dose (50, 100 or 200 mg/kg) was given on day -4 followed by the second dose (50, 50 or 150 mg/kg) on day -1. For each treatment group, blood (approximately 40 μl) was drawn on day 0 via the tail vein and was collected into BD microtainer® tubes with EDTA (BD, Franklin Lakes, NJ). The blood samples were transported in ice and were analyzed within two hours of collection using a HemaVet 950FS multispecies blood analyzer (Drew Scientific Inc., Oxford, CT). The total number of white blood cells, the number of neutrophils and the percentage of neutrophils were determined following the instructions of the manufacturer.
In vivo growth experiments. To examine the impact of neutrophils on bacterial clearance, a total of 72 mice were randomly divided into 4 groups (18 mice in each group). Each group was given a cyclophosphamide regimen as above. The mice were anesthetized by a single intraperitoneal injection of 1.25% 2,2,2-tribromoethanol (Sigma-Aldrich, St Louis, MO) at a dosage of 25 mg/kg. AB BAA 747 was grown to log-phase growth in Ca-MHB broth; the suspension was washed once and concentrated in sterile saline based on absorbance at 630 nm. The bacteria were inoculated into the trachea of anesthetized mice under laryngoscopic guidance. The inoculum (approximately $1 \times 10^6$ CFU in 10 µl) used was guided by previous investigations mimicking a clinical course of infection but no excessive mortality by 24 h. In each group, 3 mice were sacrificed by CO$_2$ asphyxiation at baseline to ascertain the infective inoculum, and 3 mice each were sacrificed at 4, 8, 12, 20 and 24 h after infection. The lungs from each mouse were aseptically collected for quantitative culture. Prior to being cultured, lungs were homogenized in 10 ml of sterile saline. The homogenates were centrifuged (4°C at 4000 $\times$ g for 15 min), decanted, and reconstituted with sterile saline at 10 times the original volume. The samples were subsequently serially diluted (10×) and quantitatively plated on MHA plates. The reliable lower limit of detection was 1000 CFU/g.

In vivo growth dynamics model. The change of bacterial burden in lung tissues over time was described using a mathematical model, as shown in Figure 1. The rate of change of bacteria over time was expressed as the difference between the intrinsic bacterial growth rate and the kill rate provided by the neutrophils. Previous investigations demonstrated the growth of AB BAA 747 was not considerably impacted by nutrient depletion, so the $K_s$ value derived from the in vitro time growth experiments was adopted (data not shown). Additional model parameters were used to account for other relevant physiological phenomena such as...
contact inhibition (using a maximum population size) and non-linear (sigmoidal) kill rate to account for saturable killing. The killing profiles in all animal groups were co-modeled by the ADAPT II program (1).

**Prospective validation of mathematical model.** The above in vivo growth experiment was repeated using PAO1. An inoculum of approximately $1 \times 10^3$ CFU (in 10 µl) was used. Four mice were sacrificed at baseline to ascertain the infective inoculum and 4 mice in each group were sacrificed at 24 h as described above.

**RESULTS**

**In vitro time-growth studies.** The best-fit growth rate constant ($K_g$) of AB BAA 747 in full-strength Ca-MHB was $1.463 \pm 0.191$ h$^{-1}$ (mean ± standard deviation). Previous experiments demonstrated the growth courses in various strengths (full-strength and 0.1-strength) of broth were similar, indicating that the growth of AB BAA 747 was not considerably impacted by nutrient depletion (data not shown). In contrast, the growth rate constants ($K_g$) of PAO1 in full-strength and 0.1-strength Ca-MHB were found to be $1.509 \pm 0.014$ h$^{-1}$ and $1.047 \pm 0.015$ h$^{-1}$, respectively.

**Determination of absolute neutrophil count.** The ANC values of animals given cyclophosphamide are shown in Figure 2. Compared to the control animals, a graded neutropenia was successfully induced by the cyclophosphamide regimens. The neutrophil count was reduced approximately 90% after administrations of 200 mg/kg and 150 mg/kg of cyclophosphamide. For the other two treatment groups, the percentages of ANC reduction were approximately 70% and 20%, respectively.
**In vivo growth experiments.** A consistent baseline tissue burden (ranged from 7.07 to 7.32 log CFU/g) was achieved. The dynamic change of bacterial burden in lung tissues over time is displayed in Figure 3. A divergence of bacterial burden profiles was observed after 8 h. At 24 h, the net change of bacterial burden from baseline ranged from -1.08 log CFU/g to 1.72 log CFU/g. The bacterial burden observed was negatively correlated the ANC achieved in the animals. A net growth in bacterial burden was observed in animal groups given 200/150 and 100/50 mg/kg of cyclophosphamide (1.72 and 0.56 log CFU/g, respectively). On the other hand, a net reduction of 0.52 and 1.08 log CFU/g was seen in animals given the 50/50 mg/kg regimen and the control animals, respectively.

**Mathematical modeling of in vivo data.** Overall, the model fit to the data was satisfactory ($r^2 = 0.945$) based on the best-fit parameter estimates (Figure 4). The best-fit maximal kill rate by neutrophils ($K_\alpha$) was 1.743 h$^{-1}$. In addition, the number of neutrophils necessary for 50% maximal killing was 190.8/mm$^3$ and the maximal population size was $1.82 \times 10^9$ CFU/g, respectively. The best-fit relationship between the killing rate and ANC is shown in Figure 5A.

**Prediction and validation of mathematical model.** A baseline tissue burden ranging from 3.10 to 3.51 log CFU/g was achieved. The behavior of PAO1 with similar cyclophosphamide preparatory regimens was predicted using the best-fit parameter estimates. The best-fit kill rate was compared to the growth rates of the bacteria, as shown in Figure 5A. Qualitatively, PAO1 was expected to be suppressed in 2 out of 4 experimental groups (the control group and the dosing group given 50/50 mg/kg cyclophosphamide), using the $K_\alpha$ value derived from experiments using full-strength Ca-MHB. Alternatively, it was predicted that 1 out of 4 experiment groups (the dosing group given 200/150 mg/kg of
cyclophosphamide) would not be suppressed, using the $K_g$ value derived from 0.1-strength Ca-MHB experiments. Validation experiments revealed that bacterial growth was suppressed in only 2 dosing groups (Figure 5B), attesting to the predicting performance of our mathematical model.

**DISCUSSION**

The important role of the immune system (neutrophils) in combating bacterial infections is indisputable. Several pre-clinical studies have demonstrated that depletion of neutrophils would result in a serious deficiency in bacterial clearance (15, 16, 19). In addition, retrospective cohort clinical studies have demonstrated severe neutropenia or immunosuppression was associated with higher mortality in patients (8, 17).

The quantitative impact of the immune system on bacterial clearance is not well established. Recently, an investigation delineated the impact of granulocytes on the bacterial clearance in a mouse thigh infection model (2). To the best of our knowledge, this is the only recent published study investigated the quantitative impact of granulocytes. In this study, different inocula were injected into the thighs of immunocompetent mice, and the bacterial burden changes were observed over 24 h. A mathematical model was used to elucidate the impact of bacterial burden on bacterial clearance by granulocytes. The authors concluded that bacterial kill by granulocytes was saturable and a higher reliance on chemotherapy would be necessary to drive clearance of a high bacterial burden.

In this study, we attempted to capture the quantitative impact of neutrophils in bacterial infections. Instead of just relying on an early and late observation, we observed the growth course of bacteria serially over 24 h to more closely track the dynamic change of
bacterial burden. Also, escalating cyclophosphamide regimens were used to produce graded
immunosuppression in the animals. This would allow us to assess the quantitative
relationship between neutrophil counts and bacterial killing with more precision. Finally, in
addition to fitting the experimental data, the mathematical model also provided a reasonable
prediction on the bacterial growth / suppression of another bacterium under similar
experimental conditions.

Several assumptions were made in the model. One assumption was the in vivo
bacterial growth rate was identical to that derived from our in vitro time-growth
investigations. Conceptually, it was regarded as the in vivo maximal growth rate in the
absence of neutrophils. The growth rate constant of AB BAA 747 was derived from
experiments using full-strength Ca-MHB, which was similar to that obtained using
0.1-strength Ca-MHB previously. However, nutrient depletion appeared to influence the
growth of PAO1 to a greater extent. We were unsure which growth rate constant would be
more realistic under in vivo conditions. Nonetheless, observations in the validation
experiments seemed more reliable using the value from full-strength Ca-MHB. Secondly, the
ANC data on day 0 was used solely to represent the impact of neutrophils. Although
neutrophil recruitment to the infection site is expected following bacterial inoculation, we did
not expect the neutrophil count would increase dramatically within a short period of time.
Thus, our assumption was deemed reasonable for the timeframe of the experiments (24 h).
Finally, we assumed that neutrophil was the only immune component responsible for
bacterial clearance, and there was no substantial residual killing from other immune
components such as antibodies or the complement system. Residual killing was previously
considered during the model development stage, with the use of additional model
parameter(s). However, these hierarchically more complex mathematical models did not
11 improve predictions of the validation experiments and was thus abandoned.

The model predictions were reasonable in predicting bacterial behavior in vivo in a qualitative sense. There were several limitations in this study, which could have affected the predicting ability of the model. Observations of ANC on the day of infection could only be made with ANC > 200 cell/mm$^3$ (approximately 90% neutrophils reduction from baseline). As such, it was difficult for us to fully define and assess the necessity to incorporate residual killing from immune components other than neutrophils. We have briefly investigated a cyclophosphamide dosing regimen higher than 200/150 mg/kg (the highest reported in this study). However, it was found to be associated with excessive mortality (likely due to drug toxicity) and thus it was not further pursued (data not shown). Another limitation of the study was the bacterial inocula used. In contrast to the previous investigation (2), we did not evaluate the impact of neutrophils on the bacterial clearance for different inocula. Finally, only two representative Gram-negative bacteria were examined. Further studies in other clinically important pathogens (e.g., *Staphylococcus aureus, Streptococcus pneumoniae*) could further validate the utility of the proposed mathematical model.

In conclusion, our quantitative results provided new insights of the impact of neutrophil on bacterial clearance. The mathematical model established in the study may be used as a foundation to investigate the impact of other immune components on various bacterial species. Furthermore, the beneficial effect of neutrophils in combination with antimicrobials should be investigated.
The authors thank Alice Chen and Allison Rosen for technical assistance in blood cell profiling. The study was partially supported by the National Science Foundation (CBET-0730454).

Figure 1. In vivo bacterial growth dynamics model

Population balance for a bacterial population:

Rate of change of bacteria over time = Intrinsic growth rate – Kill rate by neutrophils

\[ \frac{dN(t)}{dt} = G[N(t)] - K[ANC, N(t)] \]

where:

\[ G[N(t)] = K_g \left[ 1 - \frac{N(t)}{N_{\text{max}}} \right] N(t) \]

\[ K[ANC, N(t)] = \left( \frac{K_1 \cdot ANC}{ANC + ANC_{50k}} \right) \cdot N(t) \]

- \( K_g \) – growth rate constant for bacterial population
- \( N(t) \) – concentration of bacterial population at time \( t \)
- \( N_{\text{max}} \) – maximum population size
- \( K_1 \) – maximal kill rate constant for bacterial population by neutrophils
- \( ANC_{50k} \) – ANC to achieve 50% of maximal kill rate for bacterial population
