Abstract

We describe a calorimetric assay for detection of voriconazole-resistant *Aspergillus fumigatus* within 8 h. Among 27 genetically distinct strains, all 21 resistant and all 6 susceptible strains were correctly identified by measurement of fungal heat production in presence of voriconazole. This proof-of-concept study demonstrates the potential of microcalorimetry for rapid detection of azole-resistance in *A. fumigatus*. 
Voriconazole is the first-line treatment agent against invasive aspergillosis (1). The prevalence of azole-resistant *Aspergillus fumigatus* strains is continuously rising, highlighting the need for rapid antifungal susceptibility testing (2). Azole-resistance can emerge during long-term antifungal therapy, or can be induced in environmental isolates by the use of agricultural fungicides (3-5). Resistance is mainly caused by mutations in the *cyp51A* gene at codons G54, L98, G138, M220, G432, and G448 (6), of which L98 in combination with a tandem repeat at codon 34 being the most prevalent one. The TR34/L98 mutation induces pan-azole resistance, whereas isolates harboring other mutations may remain susceptible to voriconazole and posaconazole despite resistance to itraconazole. The new environmental mutation TR46/Y121F/T289A, which at present is only described from the Netherlands, Belgium and India, conveys resistance to voriconazole and variable resistance to other azoles (7-9). Different PCR assays for screening of mutations in the *cyp51A* gene have been described but none of them are currently commercially available (10, 11).

The principle of microcalorimetry is based on the measuring of microbial heat production related to growth and metabolism (12). Recently, the potential of isothermal microcalorimetry was studied in a microbiology setting, including the differentiation between methicillin-susceptible and methicillin-resistant *Staphylococcus aureus* within 5 h (13), susceptibility testing of *Aspergillus* and non-*Aspergillus* spp. (14, 15) and evaluation of antifungal combinations against *Aspergillus* spp. (16). In this study, we investigated the potential of microcalorimetry for rapid detection of voriconazole-resistance in *A. fumigatus*, using genetically characterized resistant mutants.

A collection of 26 *A. fumigatus* clinical and environmental isolates was investigated. *A. fumigatus* ATCC 204305 was included for quality control (voriconazole MIC 1 μg/mL).
Sequence-based analysis of the Cyp51A gene (4, 17) showed that twenty isolates harbored the TR34/L98 mutation, and two isolates a mutation at position G54 (G54E/W), exhibiting voriconazole MICs of 4-8 μg/mL and 0.5 μg/mL, respectively. *A. fumigatus* was identified
based on macroscopic and microscopic morphologic features and confirmed by sequencing of the internal transcribed spacer region, \( \beta \)-tubulin gene and calmodulin gene (5). Voriconazole MICs were determined by microbroth dilution according to EUCAST guidelines (\( S \leq 1 \mu g/mL, R > 2 \mu g/mL \)) (18).

For microcalorimetry, 3 mL Sabouraud dextrose broth (SDB) (Oxoid CM0147; Basingstoke, Hampshire, UK) containing serial dilutions of voriconazole (Pfizer Pharma AG, Zurich, Switzerland) was used, leaving 1 mL air in the headspace of the calorimetric glass ampoule. SDB without voriconazole was used for growth control. An inoculum of \( \approx 2.5 \times 10^5 \) conidia/mL was used, determined by microscopic enumeration using a hemocytometer. Air-tightly sealed ampoules were introduced into the isothermal microcalorimeter (TAM III, TA Instruments, Newcastle, DE, USA) and measurements were performed every ten seconds at a temperature of 37°C (accuracy of the thermostat was \( 10^{-5} ^\circ C \)). The detection threshold was determined at 20 \( \mu W \) to distinguish fungal heat production from the thermal background noise (i.e. growth media without molds). The time to reach 20 \( \mu W \) was monitored (in h). Data analysis was done with the manufacturer’s software (TAM Assistant, TA Instruments) and GraphPad Prism 6.0 (GraphPad Software, La Jolla, CA, USA). For statistical analysis the Mann-Whitney U test and the Fischer’s test of equality of variances were performed.

Figure 1 shows typical heat-flow curves of a voriconazole-susceptible (A) and voriconazole-resistant (B) strain. With increasing voriconazole the time to reach the detection limit was delayed, with a concentration of 1 \( \mu g/mL \) completely inhibiting the heat-flow of the susceptible strain. In contrast, growth-related heat of the resistant strain was detected even in the presence of the highest voriconazole concentration (8 \( \mu g/mL \)) tested.

The mean heat-detection time (± standard deviation [SD]) in absence of voriconazole was 5.13 ± 1.38 h and 4.23 ± 0.97 h for susceptible and resistant strains, respectively. As previously reported (19), there was no reduction in fitness and growth rate among the azole-
resistant strains harboring TR34/L98 or G54 mutations as compared with the susceptible isolates (p = 0.13). A nutrient-rich culture medium (SDB) was used in order to support optimal growth and thereby rapidly achieve a heat signal. Most recommended assays for detection of resistance are based on RPMI culture, which is a suboptimal medium for growth of clinical Aspergillus isolates, and growth conditions were therefore optimized. Figure 2 shows the time to heat detection of susceptible (S) and resistant (R) A. fumigatus strains in the presence of voriconazole at increasing concentrations. In the presence of 0.5 μg/mL voriconazole, the mean detection time (± SD) increased to 41.32 ± 5.65 h for susceptible strains compared to 5.38 ± 1.63 h for resistant strains (p = 0.0003). The minimal time for detection voriconazole-resistant strains was 8 h, as indicated by the horizontal dotted line. At a concentration of 1 μg/mL, voriconazole inhibited growth of all susceptible strains for 48 h, whereas all resistant strains were detected within 12 h, with a mean detection time of 7.35 ± 2.43 h. At higher concentrations of voriconazole (2, 4 and 8 μg/mL), the detection time for resistant strains increased to 20.10 ± 14.71 h, 32.10 ± 12.58 h and 42.19 ± 10.19 h, respectively. For the resistant isolates, the variance in detection time was larger at voriconazole concentrations ≥2 μg/mL, than at concentrations ≤1μg/mL (p <0.0001), indicating that there is a difference in antifungal resistance also among fungal isolates harboring the same mutation. At concentrations of 2, 4 and 8 μg/mL, the variance was not significantly different (p >0.05) in between the groups.

This proof-of-concept study demonstrates the potential of microcalorimetry for rapid detection of azole-resistance in A. fumigatus. Resistant strains were distinguished from susceptible ones within 8 h in the presence of 0.5 μg/mL voriconazole in SDB. Among 27 genetically distinct fungal isolates, 21 of 21 resistant and 6 of 6 voriconazole-susceptible A. fumigatus were correctly identified. Compared to PCR-based assays, the microcalorimetric susceptibility assay allows rapid and accurate detection of resistance without the need of
knowledge of the target sequence. This is particularly important in the light of recent reports of new and previously unknown mutations leading to azole resistance [7, 8, 20-22]. The importance of this report is the novel principle of susceptibility testing, which is based on heat detection instead of currently used visible growth or molecular testing assays. By standardization and optimization of the microcalorimetric assay, azole resistance could possibly be detected directly from patient cultures, rather than from pure laboratory cultures. In order to introduce microcalorimetry in a clinical laboratory setting, technical development is needed to allow automated, cost-efficient and high-throughput susceptibility testing.

Parts of the results were presented at the 23rd European Congress of Clinical Microbiology and Infectious Diseases, April 27-30, 2013, Berlin, Germany.

J.F.M. received grants form Astellas, Merck, Basilea and Schering-Plough. He has been a consultant to Basilea and Merck, and received speaker’s fees from Merck, Pfizer, Schering-Plough, Gilead and Janssen Pharmaceutica. A.T. received grants from Pfizer and Gilead. U.F.T.: no potential conflicts of interest.
Legends to Figures

Figure 1. Heat-flow curves of a representative susceptible (MIC 1 μg/mL) (A) and a resistant (MIC >8 μg/mL) *A. fumigatus* strain in the presence of voriconazole. The heat-detection limit of 20 μW is marked with a dashed line. Heat flow was measured for 48 h.

Figure 2. Time to heat detection of voriconazole-susceptible (n=6, circles) and voriconazole-resistant (n=21, squares) *A. fumigatus* strains in the presence of serial dilutions of voriconazole from 0 to 8 μg/mL, as measured by isothermal microcalorimetry at 37°C. The numbers indicate the mean detection time in hours. The dotted horizontal line indicates the optimal time (8 h) for distinguishing azole-susceptible and azole-resistant strains in the presence of 0.5 μg/mL of voriconazole.
