Received 23 May 2000/Returned for modification 20 August 2000/Accepted 1 October 2000

**Binding affinities of  $\beta$ -lactam antibiotics for the three penicillin binding proteins (PBPs) from *Chlamydia trachomatis* were determined in vitro and compared with their antichlamydial activities. Mecillinam selectively inhibited PBP1, with a 50% inhibitory concentration for PBP1 binding (0.2  $\mu$ g/ml) similar to the MIC (0.1  $\mu$ g/ml) and minimum bactericidal concentration (0.25  $\mu$ g/ml). Although the other  $\beta$ -lactams inhibited a wider range of PBPs than mecillinam, their antichlamydial activities were inferior to that of mecillinam.**

Chlamydiae are an important group of gram-negative intracellular pathogens which cause serious infections in humans (18). They have a complex development cycle involving infection by elementary bodies (EBs), transformation of EBs into reticulate bodies (RBs), RB division, differentiation of RBs back to EBs, and release of EBs following host cell lysis (18). Penicillin and other  $\beta$ -lactam antibiotics inhibit the growth of chlamydiae (1, 3, 8–10, 13–16) and have been used for the treatment of chlamydial infections, particularly when first-line agents are contraindicated (11, 14, 19, 24, 25). Exposure of chlamydiae to penicillin leads to the accumulation of large aberrant RBs, the so-called penicillin forms, which can resume normal development if penicillin is removed (15, 16). Consequently, it has been suggested that  $\beta$ -lactam antibiotics interfere with RB division (1, 3, 16).

The susceptibility of chlamydiae to  $\beta$ -lactams is consistent with the presence of penicillin binding proteins (PBPs) in these organisms (1, 3, 7, 12, 21). In other bacteria PBPs have roles in peptidoglycan (PG) metabolism through their activities as transpeptidases, carboxypeptidases, and endopeptidases (6, 23). Chlamydiae possess three PBPs, and although genomic analysis assigns transpeptidase activity to PBP1 and PBP2 (3, 7) and carboxypeptidase activity to PBP3 (3, 7), a major paradox of chlamydial biology is the inability to detect PG, or a PG-like polymer, in these organisms (1, 3, 7, 16). Furthermore, the apparent absence of genes encoding transglycosylase activity suggests that if a muramic acid-containing wall polymer is synthesized by chlamydiae, then it may exist only as a cross-linked disaccharide-peptide, i.e., as a glycanless wall polymer (7). In view of these observations, there is poor understanding of the mechanisms by which  $\beta$ -lactams prevent chlamydial growth, and it is not known, for instance, whether inhibition of all three PBPs is a requirement for antichlamydial activity or whether binding to individual PBPs is sufficient for growth inhibition. We have now addressed these issues by comparing

the binding of various  $\beta$ -lactams to chlamydial PBPs in vitro with their antichlamydial activities.

We chose a panel of seven  $\beta$ -lactam antibiotics and determined their MICs, minimum bactericidal concentrations (MBCs), and affinities for PBPs in *Chlamydia trachomatis* 434 serotype L2 (Table 1). Benzylpenicillin, ampicillin, and cefotaxime were purchased from Sigma, and the other antibiotics were gifts from Merck Sharp & Dohme (imipenem, as Primaxin IV), Astra-Zeneca (meropenem), Leo Pharmaceuticals (mecillinam), and Biochemie GmbH (ceftriaxone).

*C. trachomatis* was cultured in McCoy cell monolayers which were prepared on glass coverslips in flat-bottomed plastic vials. Confluent cells were infected with  $10^3$  inclusion-forming units of *C. trachomatis* in Dulbecco's modified Eagle medium (Gibco BRL, Paisley, United Kingdom) supplemented with 4% fetal calf serum and 1  $\mu$ g of cycloheximide per ml (17). Cultures were centrifuged at  $2,000 \times g$  for 30 min at 30°C and then incubated at 37°C. At 1 h after infection, the medium was changed and the test antibiotic was added. For MBC determinations, the infected cells were scraped off the coverslips after 48 h and 0.1 ml was used to infect a second monolayer growing on antibiotic-free medium. After a further 48 h, the coverslips were fixed in methanol, stained with a fluorescein isothiocyanate-labeled monoclonal antibody to the chlamydial lipopolysaccharide (DAKO Ltd., Ely, United Kingdom), and then examined by microscopy at magnifications of  $\times 400$  and  $\times 1,000$ . The MBC was defined as the lowest concentration of antibiotic in the first cycle of infection that resulted in no inclusions in the second cycle of infection. MICs were determined as described above, but after the first 48 h of incubation the cultures were fixed in methanol and stained. The MIC was defined as the lowest concentration of antibiotic that led to the formation of inclusions with abnormal morphology, as assessed by light microscopy (Fig. 1 illustrates mecillinam as an example).

PBP assays were performed essentially as previously described (2, 20), with the modifications described below. Chlamydiae were grown in McCoy cells in 150-cm<sup>2</sup> tissue culture flasks with an inoculum that gave 95 to 100% infection without centrifugation. After 20 h, while the chlamydiae were still predominantly RBs, the medium was removed and the infected

TABLE 1. Antichlamydial activities of selected penicillins, cephalosporins, and carbapenems and their competition for the PBPs of *C. trachomatis*

Antibiotic	MIC ( $\mu\text{g/ml}$ )	MBC ( $\mu\text{g/ml}$ )	IC <sub>50</sub> ( $\mu\text{g/ml}$ ) for PBP binding		
			PBP1	PBP2	PBP3
Benzylpenicillin	0.1	4.0	0.03	0.005	0.01
Ampicillin	0.1	2.0	0.01	0.005	0.5
Mecillinam	0.1	0.25	0.2	100	250
Ceftriaxone	2.0	16.0	0.1	0.01	1.0
Cefotaxime	32.0	250	0.1	0.04	5.0
Imipenem	64	512	0.01	0.2	0.005
Meropenem	16	64	0.01	0.1	0.005

cells were scraped off into 10 ml of phosphate-buffered saline (PBS) per flask. The cells were sonicated for five 30-s cycles, and membranes were pelleted by centrifugation at  $30,000 \times g$  for 80 min at  $4^\circ\text{C}$ . The pellets were resuspended in PBS containing DNase I (25  $\mu\text{g/ml}$ ) and stored at  $-80^\circ\text{C}$ . For PBP binding assays, 10  $\mu\text{l}$  of membrane preparation (50  $\mu\text{g}$  of protein) was added to 10  $\mu\text{l}$  of  $\beta$ -lactam solution (various concentrations) in PBS. Samples were incubated at  $35^\circ\text{C}$  for 20 min, and then 2  $\mu\text{l}$  of [ $^3\text{H}$ ]benzylpenicillin (Amersham Pharmacia Biotech, Amersham, United Kingdom) (37 mBq/ml; final concentration, 0.5  $\mu\text{g/ml}$ ) was added. After a further 20 min at  $35^\circ\text{C}$ , the reaction was stopped by the addition of 20  $\mu\text{l}$  of sodium dodecyl sulfate (SDS) sample buffer (0.06M Tris-HCl, 1.4 M 2-mercaptoethanol, 4% [wt/vol] SDS, 20% [vol/vol] glycerol, 0.1% [wt/vol] bromophenol blue). Samples were boiled for 5 min and then centrifuged ( $30,000 \times g$ , 10 min,  $4^\circ\text{C}$ ). Proteins were separated by SDS-polyacrylamide gel electrophoresis, and the gels were analyzed as described previously (2) after autoradiography for 28 days using Amplify (Amersham Pharmacia) as the fluor. PBP binding assays were performed at least twice for each  $\beta$ -lactam antibiotic.

It is well documented that when *C. trachomatis* is cultured in the presence of  $\beta$ -lactam antibiotics, inclusions form with abnormal morphology (10). Since we wanted to determine the minimal concentration of antibiotic that affected chlamydial growth, we used morphological abnormality (Fig. 1) as a criterion for determining MICs, rather than complete inhibition of the development of inclusions, which has been used by

FIG. 1. Light micrograph of chlamydial inclusions growing in McCoy cells and stained with fluorescein isothiocyanate-labeled monoclonal antibody to the chlamydial lipopolysaccharide. Chlamydiae were treated with 0.25  $\mu\text{g}$  of mecillinam per ml (a) or no antibiotic (PBS control) (b). The typical appearance of the  $\beta$ -lactam form can be seen in panel a, compared to a normal inclusion in panel b. Magnification,  $\times 3,200$ .

Meropenem concentration ( $\mu\text{g/ml}$ )

FIG. 2. Fluorogram showing the competition of meropenem for the PBPs of *C. trachomatis*.

others (8, 9). Thus, the MICs that we determined (Table 1) are not necessarily directly comparable with those reported in the literature. However, in agreement with others (8, 9), we observed that representative penicillins (benzylpenicillin, ampicillin, and mecillinam) were more active at both the MIC and MBC than cephalosporins (ceftriaxone and cefotaxime). The carbapenems imipenem and meropenem were also relatively inactive, in agreement with earlier findings on *N*-formimidoylthienamycin and imipenem (8, 9). Mecillinam was the most potent of the  $\beta$ -lactams we investigated, having an MBC and an MIC of 0.25 and 0.01  $\mu\text{g/ml}$ , respectively (Table 1). Similar observations were made by Hammerschlag and Gleyzer (9), who found that mecillinam had the greatest antichlamydial activity among 12  $\beta$ -lactams studied.

The PBP pattern of RBs from *C. trachomatis* is shown in Fig. 2, together with the results of a typical competition experiment, in this case using meropenem. On the basis of electrophoretic mobility, the PBPs had apparent molecular masses of 110 kDa (PBP1), 73 kDa (PBP2), and 40 kDa (PBP3). These molecular mass values differ from those reported by Barbour et al. (1) and those predicted by sequence analysis (12, 21). We have previously commented that these differences are probably explained by anomalous migration of the PBPs in SDS-polyacrylamide gel electrophoresis (22).

Data for competition of the seven  $\beta$ -lactam antibiotics with [ $^3\text{H}$ ]benzylpenicillin for the three PBPs are presented in Table 1. As the PBP assay is based on competitive binding, these data are expressed as 50% inhibitory concentrations (IC<sub>50</sub>s), i.e., the concentration of  $\beta$ -lactam required to inhibit subsequent binding of [ $^3\text{H}$ ]benzylpenicillin by 50% (2, 4, 5). The only quantitative PBP binding data previously reported for *C. trachomatis* RBs concern the binding of benzylpenicillin, where IC<sub>50</sub>s of 0.03  $\mu\text{g/ml}$  (PBP1), 0.006  $\mu\text{g/ml}$  (PBP2), and 0.003  $\mu\text{g/ml}$  (PBP3) were reported (1). For benzylpenicillin we observed a similar range of IC<sub>50</sub>s, with no more than a sixfold difference in affinity between the individual PBPs.

Studies with other bacteria, particularly the *Enterobacteriaceae* and *Pseudomonas aeruginosa*, have indicated that the killing target or targets for a particular  $\beta$ -lactam are usually represented by those PBPs that are most readily saturated by the antibiotic (2, 4, 5, 23). On this basis, it appears that all three

chlamydial PBPs may be targets for benzylpenicillin. The other  $\beta$ -lactams appear to exhibit some selectivity towards particular PBPs. The two carbapenems had lower affinities for PBP2 than for PBP1 and PBP3, and the two cephalosporins and ampicillin had lower affinities for PBP3 than for PBP1 and PBP2 (Table 1). With the exception of mecillinam, the MIC and sometimes also the MIC were significantly higher than the PBP binding values. This suggests that the antibiotics have some difficulty in crossing the various host cell and chlamydial permeability barriers that separate the PBPs in RBs from the external medium.

Compared with the other  $\beta$ -lactam antibiotics, mecillinam exhibited a different set of responses. This antibiotic displayed high selectivity for PBP1, and the  $IC_{50}$  for PBP1 binding (0.2  $\mu$ g/ml) corresponded closely with both the MIC and MBC (Table 1). Thus, mecillinam appears to penetrate the various permeability barriers quite effectively and exerts antichlamydial activity by binding exclusively to PBP1. Furthermore, these data suggest that PBP1 is essential for chlamydial division and survival. In *Escherichia coli* mecillinam also has high affinity for a single PBP, in this case PBP2 (4–6, 23), which implies that chlamydial PBP1 and *E. coli* PBP2 may be functionally related. This is also supported by analysis of structural relatedness, since among the *E. coli* PBPs, chlamydial PBP1 has highest homology to *E. coli* PBP2 (7). Although PBP2 is required for the maintenance of cell shape in *E. coli* (4, 5, 23), the lethality of PBP2 inactivation has also been attributed to cell division inhibition (26). If chlamydial PBP1, by analogy, is involved in cell division, this would be consistent with our hypothesis (3) that in chlamydia PG, or a glycanless PG-like polymer, has a major role in RB division. Since mecillinam appears to specifically inhibit chlamydial PBP1, more detailed examination of the structure and morphology of mecillinam-inhibited cultures may provide a clue to the role of this PBP in the chlamydial cell cycle.

Finally, the results reported here support an earlier suggestion that in view of its potent antichlamydial activity, mecillinam may have a role in the treatment of chlamydial infection (9). Furthermore, our data now provide a molecular explanation for the potency of mecillinam, which can be attributed to both favorable cell penetration and high affinity for chlamydial PBP1.
