Received 27 December 2000/Returned for modification 3 June 2001/Accepted 12 August 2001

Sordarins constitute a new class of antifungal agents with a novel mechanism of action involving the selective inhibition of fungal protein synthesis. A further evolution of this class of antifungals has led to a new family of sordarin derivatives called azasordarins. The therapeutic efficacies of two new azasordarins, GW471552 and GW471558, were studied in experimental models of oral and vulvovaginal candidiasis in immunosuppressed rats. In all cases rats were immunosuppressed with dexamethasone in the drinking water. Oral candidiasis was established by inoculating 0.1 ml of a yeast suspension containing $5 \times 10^8$ cells of Candida albicans 4711E with a cotton swab on three alternate days. Vulvovaginal candidiasis was established in ovariectomized and estrus-induced rats by intravaginal inoculation of $10^7$ CFU of C. albicans 4711E in 0.1 ml of saline. GW471552 and GW471558 were administered at 1, 5, and 10 mg/kg of body weight via the subcutaneous route. In oral candidiasis, azasordarins were administered each 8 h for 7 consecutive days, while in vaginal candidiasis the compounds were given each 4 h for 3 consecutive days. Antifungal activity of azasordarins was assessed by colony counts and by histological examination 1 day after treatment. In the oral infection model, GW471552 and GW471558 administered at 5 mg/kg significantly reduced ($P < 0.05$) the number of CFU of C. albicans compared with untreated controls. In addition, GW471552 and GW471558 given at 10 mg/kg eradicated C. albicans from the oral cavities of 100% of infected animals. Against vulvovaginal infection, both compounds showed significant therapeutic efficacy. GW471552 was able to eradicate the vaginal fungal burden at a dose of 10 mg/kg, and it significantly reduced the number of CFU of C. albicans in vaginas of rats treated with a dose of 5 mg/kg ($P < 0.05$). GW471558 showed greater efficacy, eradicating the fungal burden of 100% of infected rats at a dose of 5 mg/kg and significantly reducing ($P < 0.05$) the C. albicans vaginal counts even at a dose of 1 mg/kg. In both therapeutic efficacy studies, the histological findings confirmed the microbiological results. The experimental results presented show that the tested azasordarins are effective against oral and vulvovaginal candidiasis in immunosuppressed rats and could be promising antifungal agents for use in humans.

Infections caused by Candida albicans have increased in prevalence worldwide (3, 19). These infections range from mucosal candidiasis, including oropharyngeal and esophageal candidiasis, which is frequently observed in immunocompromised patients, to vulvovaginal candidiasis (VVC), which affects a large number of otherwise healthy women (19).

Oropharyngeal candidiasis is the most common opportunistic infection in immunosuppressed individuals and is strongly correlated with impairment of the immune system. In addition, several conditions, such as hyposalivation, diabetes mellitus, and prolonged antibiotic use can predispose an individual to oral infection.

C. albicans vaginitis has been increasing in medical importance, since a significant proportion of women suffer from acute episodes and recurrent infections may often occur after therapy. It has been estimated that 75% of all women will experience an episode of Candida vaginitis once in their lifetime, with up to 5% showing recurrence (8). VVC is often associated with conditions such as diabetes mellitus, antibiotic therapy, and pregnancy, although in many cases there are no clear predisposing factors (18).

In recent years azole agents have become the drugs of choice for treating both oropharyngeal candidiasis and VVC (16, 18). However, recent studies have indicated the possibility of treatment failures associated with C. albicans resistance to azoles (4, 12). New and effective drugs are therefore needed to treat these fungal infections.

Sordarins are a new class of antifungal agents that act by inhibiting the protein synthesis elongation cycle (5, 6). Sordarin derivatives have demonstrated potent and relatively broad-spectrum antifungal activity in several in vitro (10) and in vivo (1, 13, 14) studies. A further evolution of this class of compounds has led to a new family of substances called azasordarins. Azasordarins are chemically characterized by the presence of a 6-methylmorpholin-2-yl group with different N-4' substituents at position 8a of the sordaricin indacene ring system (Fig. 1). They have demonstrated excellent activity against key fungal pathogens related to mucosal infections, such as C. albicans and other, non-C. albicans species (9a).

In order to understand the potential use of azasordarins for the treatment of mucosal candidiasis, the therapeutic efficacies of GW471552 and GW471558, as representatives of these new family of antifungal agents, have been evaluated in two exper-
mental infections models of oral candidiasis and VVC in immunosuppressed rats. Taking into account that *C. albicans* infective forms are pseudohyphae, which are able to penetrate epithelial layers, the therapeutic efficacy of azasordarins against *C. albicans* infections has been evaluated by microbiological but also by histopathological studies.

### MATERIALS AND METHODS

**Antifungal agents.** The azasordarin derivatives GW471552 and GW471558 (Fig. 1) were synthesized and supplied by the Organic Chemistry Department of GlaxoSmithKline, Tres Cantos, Spain. The compounds, as sodium salts, were individually dissolved and diluted to the appropriate concentration in sterile physiological saline solution (SPSS) immediately prior to administration. Doses of antifungal agents are given as milligrams of base per kilogram of body weight.

**Organisms and inoculum preparation.** Therapeutic efficacy studies were performed against *C. albicans* 4711E, a clinical isolate used in previous in vivo studies (1, 13, 14). *C. albicans* 4711E was stored at −80°C in Sabouraud dextrose broth containing 15% glycerol in our laboratory until used. For inoculum preparation, *C. albicans* grown on Sabouraud dextrose agar plates at the time of infection. All counts are expressed as CFU of viable organisms.

**MIC determination.** The MICs of GW471552 and GW471558 against *C. albicans* 4711E were determined by the broth microdilution method according to National Committee for Clinical Laboratory Standards methods (15).

**Animals.** Six-week-old specific-pathogen-free female Sprague-Dawley rats (Iffa-Credo Laboratories, Lyon, France) weighing approximately 200 g were used. The rats were housed in 480- by 270- by 200-mm Apec cages (Techniplast, Letica Scientific Instruments, Madrid, Spain) on corncob granules (Panlab, Barcelona, Spain). Photoperiods were adjusted to 12 h of light and 12 h of darkness daily, and the environmental temperature was constantly maintained at 21 ± 1°C. Rats were given ad libitum access to food and water. The research complied with European legislation and company policy on the care and use of animals and with related codes of practice.

**Oral candidiasis model.** Oral infection in rats was induced basically as reported by Jones and Adams (11) with some modifications (14). Rats were immunosuppressed, starting 1 week before initiation of experimental infection and continued throughout the experiment, by administering dexamethasone (Fortecortin; Merck Laboratories, Madrid, Spain) in drinking water at a dose of 0.5 mg per liter. Also, a 0.1% aqueous solution of tetracycline hydrochloride (Terramycin; Pfizer Laboratories, Madrid, Spain) was given to the animals beginning 7 days before infection. The concentration of tetracycline hydrochloride was reduced to 0.01% when the infection process was started and was maintained throughout the experiment. Experimental infection was established by inoculation of the oral cavities of the rats three times at 48-h intervals with 0.1 ml of a yeast suspension containing 5 × 10⁷ cells of *C. albicans* 4711E. Oral inoculation was performed by means of a cotton swab rolled twice over all parts of the mouth. Rats were then randomly distributed into groups of 10 animals each.

Three days after the last Candida inoculation, infected animals were sampled to quantify the number of CFU in the oral cavity (see below). The mean log₁₀ CFU and standard deviation per sample were calculated and accepted as the basal level of infection before treatment.

**VVC model.** The animal model of VVC was established based on previously described models (19, 21) with modifications to obtain a more chronic and homogeneous infection. Oral infection was induced with subcutaneous administration of estradiol (Estrogeno Neosan; SmithKline Beecham, Madrid, Spain) at a dose of 10 mg/kg 3 days before infection and subsequently maintained by subcutaneous estradiol at a dose of 4 mg/kg weekly throughout the experiment. Furthermore, animals were immunosuppressed with dexamethasone (Fortecortin; Merck Laboratories) added to drinking water at a final concentration of 2 mg per liter. Immunosuppressive treatment was also started 3 days before infection and maintained throughout the experiment. For establishment of vaginal *C. albicans* infection, female rats were anesthetized with isoflurane (Forane; Abbott Laboratories, Kent, United Kingdom), using a customized face mask device with a scavenging system, and inoculated intravaginally with 10⁷ yeast cells per 0.1 ml of sterile saline. Inoculation was performed using a micropipette with disposable tips. Infected animals were then randomly distributed into groups of 10 rats each. The vaginal *C. albicans* burden was evaluated (see below) at day 3 postinfection, 24 h before the start of treatment. The log₁₀ CFU and standard deviation per vaginal sample were calculated to yield the basal level of infection and to ensure that all animals involved in the study were homogeneously infected.

**Antifungal treatment.** Antifungal therapy was started 4 days postinfection. Groups of 10 rats each were treated subcutaneously with GW471552 or GW471558 at doses of 1, 5, and 10 mg/kg of body weight in 0.5 ml of SPSS. In the oral candidiasis model, treatment was given every 4 h for 3 consecutive days. In the VVC model, treatment was administered every 4 h for 3 consecutive days. Dosage patterns were established according to pharmacokinetic data for both compounds in rat (P. Aviles, A. Pateman, R. San Roman, M. J. Guillem, and D. Gargallo-Viola, Abstr. 40th Intersci. Conf. Antimicrob. Agents Chemother., abstr. 1690, 2000). In control groups, animals received SPSS by the subcutaneous route.

**Quantification of infection level and determination of therapeutic efficacy.** Therapeutic efficacy was assessed by microbiological and histopathological evaluation. After treatment and at least 24 h after the administration of the last dose of antifungal agents or saline, animals were sacrificed by an overdose of pentobarbital (Euthalender, Normon, Spain). From each group of 10 animals, 6 were used for microbiological assessment and 4 were subjected to histopathological examination.

(i) **Microbiology.** Drug efficacy was assessed by measuring the numbers of *C. albicans* organisms (CFU) in the antifungal treatment groups and comparing them with those of the untreated controls at the end of the experiment. Oral and vaginal samples were collected by rolling a sterile cotton swab over the oral cavity or within the vagina by a standard procedure. Samples were then suspended in 1 ml of SPSS and cultured in duplicate on Bengal Rose chloramphenicol agar (Microkit Iberica, S.A., Madrid, Spain) and incubated at 37°C for 48 h. Plates were incubated at 37°C for 48 h. The mean CFU and standard deviation per sample were calculated and accepted as the basal level of infection before treatment. The number of organisms detected by this method was 40 CFU per sample.

(ii) **Histopathology.** Twenty-four hours after the end of the treatments, the animals were sacrificed and tongues or vaginas were aseptically removed. Gross observations and photographs were made following gentle rinsing of the organs. After that, tongues and longitudinally opened vaginas were fixed again in formalin for 12 h. Finally, tongue sections and vaginal tissue were embedded in paraffin. Five-micrometer sections were obtained from the paraffin blocks and stained with both hematoxylin and eosin stain and periodic acid-Schiff (PAS) stain for fungal visualization.
C. albicans experimental oral infections. From C. albicans CFU/sample. Therapeutic effects with a certain decrease in the number of organisms when compared to the number of CFU per sample in the controls. This decrease was significant in those animals that still showed positive cultures after treatment, compared to the number of CFU per sample in the untreated group. In this case, the fungal burden reductions were 96.84 and 94.37% for GW471552 and GW471558 treatments, respectively.

(ii) Pathology. Macросcopically, all infected and untreated animals showed extensive colonization by numerous hyphae of the epithelium of the dorsal surface of the tongue, and in many areas colonization extended deeply through the superficial layers of the horny squamous layers. In relation to C. albicans infection, abundant inflammatory cells in the lamina propria were observed. Multifocal leukodiapedesis into the epithelium was observed in association with these inflammatory infiltrates in the lamina propria. In multiple areas, the intraepithelial hyphae caused keratinocyte destruction and the formation of intraepithelial microabscesses (Fig. 2). Similar results were observed in animals treated with 1 mg of antifungal compounds per kg. However, all animals treated with azasordarins at 5 mg/kg showed minimal zones of the tongue occupied by hyphae, with focal hyphal penetration that produced intraepithelial microabscesses. Animals treated with azasordarins at 10 mg/kg showed multiple regenerative areas of the covering epidermis, and no histological evidence of C. albicans within the epithelium of the tongue was seen in these animals (Fig. 3).

**Therapeutic efficacies of GW471552 and GW471558 against experimental vaginal C. albicans infections.** The therapeutic efficacies of the new azasordarins for the treatment of experimental VVC induced by C. albicans 4711E were also determined by microbiological and pathological studies.

(i) Microbiology. Ovariectomized animals were immunosuppressed with dexamethasone, and estrus was induced and maintained with estradiol. Under these conditions, vaginal colonization by C. albicans was homogeneous, with 100% of animals infected at day 3 postinfection. Before the start of antifungal treatment, the mean log CFU per sample recovered from vaginas for the global experimental population was 5.03 ± 0.3. Saline-treated controls maintained the level of infection, with vaginal counts of 4.9 ± 0.3 at 1 day after the end of treatment. The therapeutic effects of GW471552 and GW471558 treatment on the C. albicans vaginal burden in infected rats are summarized in Table 2. A significant decrease in the percentage of animals showing positive vaginal cultures

*a* Rats were orally infected with 5 × 10⁶ C. albicans 4711E cells/ml. Compounds were administered every 8 h for 7 consecutive days.

*b* NOD, no organisms detected. *P < 0.05 (versus the control treatment). The limit of detection was 40 CFU/sample.

Statistical analysis. An analysis of variance on ranks was used to statistically compare the numbers of CFU of C. albicans isolated from the mouths or vaginas of the experimental groups. Multiple comparisons of treated groups versus the control group were performed by Dunn’s method. All statistical evaluations were performed using the analysis of variance program of the SigmaStat statistical package (Jandel Scientific, Erkrath, Germany). P values of ≤0.05 were considered statistically significant. All mean values reported here include the standard deviations of the means.

**RESULTS**

Two experimental models of mucosal candidiasis, oral and vulvovaginal, were used to evaluate the therapeutic efficacies of GW471552 and GW471558. The MICs of GW471552 and GW471558 against the strain C. albicans 4711E used for experimental infections were 0.001 μg/ml for both compounds. The therapeutic efficacies of the new azasordarins were assessed by microbiological and pathological studies. Pathological examination was needed due to the ability of Candida to penetrate epithelial layers by its pseudohyphal form. From each group of 10 animals, 6 were used for microbiological assessment and 4 were used for histopathological examination.

**Therapeutic efficacies of GW471552 and GW471558 against experimental oral C. albicans infections.** (i) Microbiology. Prior to initiation of the study, samples from the oral cavity were obtained from all animals and cultured in duplicate to ensure the absence of a preexisting candidiasis. None of the rats used in the study showed any C. albicans organisms in the oral cavity. One day before antifungal treatment was started, oral swabs were taken from infected animals and cultured quantitatively as described in Materials and Methods. The results indicate that all animals developed oral infection, with a log CFU per sample (mean ± standard deviation) of 4.9 ± 0.5. This infection remained in the untreated rats, although with a certain decrease in the number of organisms when evaluated 24 h after the end of the treatment (3.2 ± 0.4 log CFU/sample). Therapeutic efficacy was assessed by comparing the numbers of C. albicans organisms recovered from mouths of antifungal-treated groups with those from the untreated control at the end of treatment. The experimental results obtained with GW471552 and GW471558 against oral candidiasis in rats are summarized in Table 1. A significant decrease in the percentage of positive cultures was observed in rats treated with GW471552 and GW471558. After antifungal chemotherapy, the challenging organism was recovered from only one-third of the animals treated with 5 mg of GW471552 or GW471558 per kg, and C. albicans was not detected in any of the animals when azasordarins were dosed at 10 mg/kg. In addition, GW471552 and GW471558 administered at 5 mg/kg significantly reduced the log number of CFU per sample in those animals that still showed positive cultures after treatment, compared to the number of CFU per sample in the controls. In this case, the fungal burden reductions were 96.84 and 94.37% for GW471552 and GW471558 treatments, respectively.

(ii) Pathology. Macroscopically, all infected and untreated animals had clinically manifest lesions of the lingual mucosa, consisting of patchy areas of smooth mucosa and well-delimited atrophic areas on the dorsum of the tongue. These lesions were mainly distributed surrounding the giant conical papillae. However, animals treated with GW471552 and GW471558 at 10 mg/kg showed grossly normal dorsal tongue surfaces. Rats treated at doses of 1 and 5 mg of azasordarins per kg showed moderate macroscopic lesions of the tongue. Evident agreement between antifungal chemotherapy and gross observations was obtained.

The histological findings for infected and untreated animals showed extensive colonization by numerous hyphae of the epithelium of the dorsal surface of the tongue, and in many areas colonization extended deeply through the superficial layers of the horny squamous layers. In relation to C. albicans infection, abundant inflammatory cells in the lamina propria were observed. Multifocal leukodiapedesis into the epithelium was observed in association with these inflammatory infiltrates in the lamina propria. In multiple areas, the intraepithelial hyphae caused keratinocyte destruction and the formation of intraepithelial microabscesses (Fig. 2). Similar results were observed in animals treated with 1 mg of antifungal compounds per kg. However, all animals treated with azasordarins at 5 mg/kg showed minimal zones of the tongue occupied by hyphae, with focal hyphal penetration that produced intraepithelial microabscesses. Animals treated with azasordarins at 10 mg/kg showed multiple regenerative areas of the covering epithelium, and no histological evidence of C. albicans within the epithelium of the tongue was seen in these animals (Fig. 3).
was observed in rats treated with both azasordarins. GW471552 and GW471558 were both able to reduce the vaginal C. albicans burden to below the detection threshold in 100% of animals treated at 10 or 5 mg/kg, respectively. Only one-third of animals treated with GW471552 at 5 mg/kg showed positive Candida cultures. In this case, animals still positive for vaginal Candida presence showed a statistically significant (P < 0.05) reduction in fungal burden compared to controls, with a log CFU per sample of 1.7 ± 0.2, which represents a 99.94% decrease in fungal burden. In the present study, GW471558 showed the greatest antifungal activity. In animals treated with GW471558 at a dose of 1 mg/kg, the challenging microorganism was recovered in only 50% of the animals at the end of antifungal treatment. In addition, animals with positive cultures in this case showed C. albicans vaginal counts significantly lower than those obtained from control animals, with a log CFU per sample of 2.6 ± 0.1, which represents a 99.50% decrease in yeast burden compared to the saline-treated controls (Table 2).

(ii) Pathology. In each antifungal-treated group and among the controls, four animals were subjected to histopathological examination of the vaginal mucosa after the end of treatment. Untreated control rats showed abundant growth of Candida organisms, both as budding yeasts and in the pseudohyphal form, involving the stratum corneum and the luminal keratin debris and accompanied by a minimal inflammatory cell response with characteristic leukocyte microabscesses (Fig. 4). In those experimental groups where C. albicans was still detectable by microbiological means, histopathological findings remained similar to those found in untreated control animals. Some Candida pseudohyphae could be observed penetrating the vaginal epithelium, with a qualitative reduction of fungal luminal presence (data not shown). On the other hand, animals treated with GW471552 and GW471558 at 10 and 5 mg/kg, respectively, that did not show positive cultures showed an absence of Candida (either as budding yeast or in the form of pseudohyphae) in the vaginas. Histopathological findings in animals treated with GW471558 illustrated this result (Fig. 5). Only residual inflammatory infiltrates and ulcerations indi-

cated that a previous infectious process was affecting the vaginal mucosa. Regenerative changes associated with the restoration of the vaginal mucosa to its normal status following antifungal treatment could also be seen.

DISCUSSION

Infections caused by *C. albicans* and a few other related species have increased in prevalence worldwide. They range from mucosal diseases observed in immunosuppressed patients to fatal systemic episodes in severely neutropenic subjects. Although oral candidiasis is not a life-threatening disease, the sustained immunosuppression in these patients facilitates recurrence of the infection. On the other hand, VVC also affects a large number of otherwise healthy women. It has been estimated that 75% of all women of childbearing age will experience an episode of VVC in their lifetime (8).

Sordarins constitute a new class of antifungal agents that are distinguished from other antifungal compounds, such as polyenes, azoles, or allylamines, in that they possess a novel mechanism of action. Sordarin derivatives are highly selective fungal protein synthesis inhibitors that interact with translation elongation factor 2 (5, 6) and the large ribosomal subunit stalk rpP0 (7), thus inhibiting translation elongation in fungal cells. This multiple interaction with elements of the translation machinery may explain the high selectivity of this novel class of antifungal agents (7). Sordarins exhibit broad-spectrum and potent in vitro (10) and in vivo (2, 9, 13) antifungal activity. The presence at position 8a of the sordarinic indacene ring system of a 6-methylmorpholin-2-yl group with different N-4′ substituents instead of the sugar moiety has lead to the development of a new class of molecules called azasordarins. With the aim of assessing the in vivo efficacies of azasordarins, two new compounds, GW471552 and GW471558, have been selected and evaluated against oral candidiasis and VVC in rats. Both animal models were selected because they appear to closely mimic the situation seen in clinical settings; therefore rats were rendered neutropenic by the addition of dexamethasone in the drinking water. These animal models were also of interest because they provide preliminary information about the tissue distribution of the compounds. Furthermore, oral and vaginal candidiasis models have been shown to afford a simple, reliable, and highly reproducible method for studying the efficacies of new antifungal agents (17, 20). On the other hand, strain-related differences in *C. albicans* pathogenicity in the rat mucosa have been described; consequently, we have used a well-characterized *C. albicans* strain that has been widely used in previous therapeutic and pharmacodynamic studies in rodents, where its pathogenic properties have been well characterized (1, 13, 14). In the present study, immunosuppression in the VVC model ensured homogeneous and chronic infection in the rats.

The data presented indicate that azasordarins GW471552 and GW471558 administered to immunosuppressed rats with

FIG. 4. VVC in control immunosuppressed rats. PAS staining was used. (a) *C. albicans* organisms are plentiful inside the vaginal cavity, and hyphae are adhering to the surface of the epithelium (arrowheads). Magnification, ×100. (b) *C. albicans* penetrating into the epithelium and causing necrosis on the superficial keratinocyte layer associated with intraepithelial leukocyte microabscesses (arrowheads). Magnification, ×400.

FIG. 5. VVC in immunosuppressed rats treated with GW471558 at 10 mg/kg. PAS staining was used. (a) *C. albicans* was not observed in treated rats. Ulceration of the covering vaginal epithelium with fibrin deposits in the lumen (arrowhead) and an important inflammatory response of the lamina propria (asterisk) were observed. The transition between mucosal ulceration and adjacent vaginal epithelium is shown by the arrow. Magnification, ×100. (b) Regenerative changes of the vaginal epithelium were observed in this area (arrows). Also observed was the development of a granulation tissue (asterisk) in the ulcerate lamina propria. Magnification, ×400.
oral candidiasis or VVC exerted a clear therapeutic effect. In
the oral candidiasis model, azasordarins reduced fungally me-
diated oral cavity injury, as measured by colony counts, gross
pathology, and histological examination. Animals given lower
dooses of GW471552 and GW471558 (1 mg/kg) showed persis-
tent C. albicans culture positivity, as well as abundant mycelial
penetration into the epithelium of the tongue. However,
GW471558 at a dose of 5 mg/kg showed a significant decrease
in C. albicans CFU obtained from the mouths of infected rats
compared with the controls, and in fact there was a reduction of
the number of infected animals after treatment (only one-
third of treated animals had positive cultures). In these ani-
mals, the histological study demonstrated that Candida organ-
isms had disappeared from the surface of the tongue, although
some hyphae persisted within the most superficial keratinocyte
layers. Agreement between cultures from the oral cavity and
the clinical and histological evidence of infection was observed.
Rats treated with 10 mg of GW471552 or GW471558 per kg
showed negative mouth cultures for all animals inspected and
a complete absence of C. albicans on the dorsal surface of the
tongue, suggesting that azasordarins at this dose were
extremely effective.

Regarding activity against VVC, GW471552 and GW471558
showed efficiencies similar to those against oral candidiasis. Both
compounds diminished the vaginal Candida burden to below
the level of detection in all treated animals when administered
at a dose of 10 mg/kg. GW471558 was the most effective com-
pound, being able to eradicate C. albicans from vaginas of infected
animals at a dose of 5 mg/kg and significantly reducing
the fungal burden when administered at a dose of 1 mg/kg
(99.5% reduction compared with untreated infected controls).
In this case, the challenging organism was recovered from only
50% of treated rats. Significant efficacy was also achieved with
GW471552 administered at 5 mg/kg, with a fungal burden
reduction of 100% in two-thirds of treated animals and of
99.94% in the remainder. In all cases evaluated, histopatho-
logical examination agreed with the microbiological results,
showing the absence of Candida (no budding yeast forms or
pseudohyphae) in those experimental groups where the micro-
organism was not detected by culture following the treatment
period. Animals given GW471552 and GW471558 at doses
leading to Candida eradication (10 and 5 mg/kg, respectively)
showed histopathological findings (such as residual inflamma-
tory infiltrates) that were clearly associated with normal mu-
cosal recovery from the induced infectious process.

In addition to the above-described considerations, the pre-
liminary in vitro and in vivo toxicity profiles of the azasordarins
reflected the low toxicity of this new family of compounds (E.
Herreros, A. Martinez, M. J. Almela, E. Jimenez, S. Lozano,

In conclusion, these results together with the good in vitro
antifungal activities of GW471552 and GW471558 (9a)
strongly suggest that azasordarins could be promising antifun-
gal agents for the treatment of human oral candida and VVC
infections.

ACKNOWLEDGMENTS
A. Martinez and S. Ferrer contributed equally to the work presented
in this publication.

We thank Jesus Caballero and members of the Pharmacological
Research Center for their excellent technical assistance, Esperanza
Herreros for providing all in vitro data, and members of the Organic
Chemistry Group for compound synthesis.
