Abstract.

The toxicity and antileishmanial effectiveness of a novel liposome formulation of meglumine antimoniate have been investigated in mongrel dogs with visceral leishmaniasis (VL) obtained from an endemic region for VL in Brazil. Groups of 12 animals received by i.v. route four doses (with 4 days-intervals) of either liposomal meglumine antimoniate (GI, 6.5 mg Sb/kg/dose), empty liposomes (GII) or isotonic saline (GIII). Evaluation of markers of hematopoietic, hepatic and renal functions before and just after treatment showed no significant change. On the other hand, transitory adverse reactions, including prostration, defecation, tachypnea and sialorrhea, were observed during the first 15 min after injections in GI and GII. Parasitological evaluation of sternal bone marrow four days after the last dose showed a significant reduction of parasite burden in GI, compared to the other groups. Immunocytochemical evaluations of the skin, bone marrow, cervical lymph nodes, liver and spleen of dogs for parasites, 150 days after treatment, indicated significant parasite suppressions (higher than 95.7%) in the lymph nodes, liver and spleen of GI, when compared to control groups. Feeding of Lutzomyia (L.) longipalpis phlebotomines on dogs from GI, 150 days after treatment, resulted in a significant reduction of sand fly infection efficiency, when compared to feeding on animals from GII and GIII. This is the first report of both long-term parasite suppression and reduction of infectivity to sand flies in naturally-infected dogs, following treatment with a liposome-encapsulated drug. Importantly, this was achieved using 20-fold lower cumulative dose of Sb, when compared to conventional antimonial treatment.
INTRODUCTION

The leishmaniases are a group of diseases produced by invasion of the reticuloendothelial system of a mammalian host by a parasite of the genus *Leishmania*. This parasite is found as a motile promastigote in the sand fly and transforms into an amastigote when engulfed by host macrophages (1). Visceral leishmaniasis (VL) is the most severe form of the disease, causing death of humans if not treated. The pentavalent organoantimonial complexes, meglumine antimoniate and sodium stibogluconate, are the first line drugs for the treatment of all forms of leishmaniasis (9). The achievement of a complete cure in dogs with VL, or at least the blockade of infectivity to sand fly, is currently a great challenge, since dogs are the main reservoir for the transmission of VL to humans and respond poorly to conventional treatment with pentavalent antimonials (2).

In the seventies, a major advance occurred when it was found that liposome-encapsulated antimonial drugs were hundreds of times more effective than unencapsulated ones for the treatment of experimental visceral leishmaniasis (VL) (5). This spectacular effect of liposome encapsulation was attributed to the drug sustained release property of liposomes and to their natural tendency to be cleared from the circulation by the fixed macrophages of the mononuclear phagocyte system (MPS), mainly the liver, spleen and bone marrow, which are major sites of parasite infection. Similar results were obtained with other antileishmanial agents (4, 29) and other vesicular systems made from non-ionic surfactants (7), instead of phospholipids.

Much effort has also been devoted to the evaluation of liposomal formulations in dogs (12, 13, 30, 33, 36-38, 44, 45), however, very few studies used the clinically-relevant naturally-infected dogs and none performed important parasitological evaluations, such as determinations of skin parasite load and dog infectivity to sand flies.
Despite the need to improve antimonial chemotherapy and the extremely promising results obtained with liposomes in experimental models of VL, no pharmaceutical composition associating liposomes and antimonials has reached commercialization so far. This fact can be attributed, at least in part, to the technological difficulties usually encountered in the preparation of stable liposomal composition for water-soluble substances. This is in contrast with the lipophilic fungicidal and leishmanicidal drug, amphotericin B, whose liposomal formulation, called AmBisome, has recently been approved by the Food and Drug Administration for treatment of VL (27). On the other hand, the high cost of the latter formulation turns difficult its large-scale use in developing countries. Furthermore, although AmBisome did promote clinical and parasitological improvements in dogs naturally infected with *Leishmania infantum*, cure was not achieved (33).

Novel liposomal formulations of meglumine antimoniate have recently been described, that are obtained through rehydration of freeze-dried empty liposomes with an aqueous solution of the antimonial compound (18-20, 38). A significant technological advantage of this method over conventional ones (3, 35) is that liposomes may be stored as pre-formed freeze-dried empty vesicles and that rehydration may be performed just before use. Two liposomal formulations differing in their mean vesicle diameter were obtained (38). The large sized formulation (mean hydrodynamic vesicle diameter of 1200 nm) was previously evaluated in dogs with VL (14, 37). Following multiple dose-regimen, this formulation resulted in a significantly lower number of positive dogs (compared to the group of dogs treated with empty liposomes or that of untreated dogs), but was unable to clear *Leishmania* parasites from the bone marrow, suggesting that this tissue may be critical for the treatment with this liposomal formulation.
In a recent study, the pharmacokinetics of the small sized liposomal formulation of meglumine antimoniate (mean hydrodynamic vesicle diameter of 410 nm) was evaluated in mongrel dogs naturally infected by *Leishmania (L.) chagasi*. Importantly, this formulation was found to target antimony to the bone marrow of dogs at a 3-fold higher level, when compared to the formulation of meglumine antimoniate in large sized liposomes (38), suggesting that it may clear more effectively parasites from this tissue.

The aim of the present study was to evaluate the small sized liposomal formulation of meglumine antimoniate in dogs naturally infected by *Leishmania (Leishmania) chagasi* for its side effects and its antileishmanial efficacy. In addition to the clinical evaluation of dogs, complete parasitological evaluations were performed through determination of the parasitic load in the liver, spleen, bone marrow, lymph nodes and skin as well as of the infectivity of dogs to sand flies.

**MATERIALS AND METHODS**

**Animals.** Fifty mongrel dogs (weighing 8-15 kg) of unknown age naturally infected with *L. (Leishmania) chagasi*, exhibiting different clinical forms of canine leishmaniasis (26), were identified and captured during an epidemiological survey carried out by Control Zoonosis Center in Santa Luzia City Hall (Minas Gerais state, Brazil Southeast). The animals manifested the classical clinical signs of canine leishmaniasis. Lymphoadenopathy was the most frequent, followed by skin disorders which included, in decreasing order of frequency, hipotricosis/alopoeia, dull fur, exfoliative dermatitis and skin ulcers.
The serological diagnosis was established by the Serology Laboratory of the Institute of Biological Sciences, Federal University of Minas Gerais (UFMG) by indirect immunofluorescence assay (IFAT) and enzyme-linked immunosorbent assay (ELISA). All animals were found to be positive by IFAT (≥1:40 dilutions) and ELISA (optical density >0.100; ≥1:400 dilutions). In addition, parasitological diagnosis was performed by observation of parasite forms in both cytological examinations and/or cultures of bone marrow aspirates in Novy-Nicolle-McNeal (NNN) enriched with minimum essential medium (α-MEM). Prior to treatment, the animals were maintained in quarantine in kennels and were treated for intestinal helminthic infections (Canex composto®, Vetbrands Health Animal), ectoparasites infestations (Front Line®, Merial) and immunized against viral infections (Defensor® and Vanguard® HTLP 5/CV-L, vaccine Pfizer, Brazil). During the whole experimental period, the dogs were housed in a screened kennel to avoid reinfection and received drinking water and a balanced feed ad libitum (Pedigree Champ®, Effem). The present research adhered to the Principles of Laboratory Animal Care (NIH publication #85-23, revised in 1985) and received approval from the Ethical Committee for the use of Experimental Animals (CETEA) of the UFMG (Brazil) protocol nº 123/05.

**Materials.** Cholesterol (CHOL) and dicetylphosphate (DCP) were purchased from Sigma Co. (St. Louis, MO, USA). Distearoylphosphatidylcholine (DSPC) was obtained from Avanti Polar Lipids Inc. (Alabaster, AL, USA). N-methyl-D-glucamine and antimony pentachloride (SbCl₅, 99%) were obtained from Aldrich Chemical Co. (Milwaukee, Wis, USA).

**Preparation of meglumine antimoniate.** Meglumine antimoniate was synthesized as previously described (16, 17) from an equimolar mixture of N-methyl-D-glucamine and pentavalent antimony oxyhydrated in water. The resulting product contained approximately 29% of antimony
by weight, as determined by plasma emission spectroscopy (ICP-OES) using a Perkin-Elmer Optima 3000 plasma emission spectrometer.

**Preparation and characterization of meglumine antimoniate-containing liposomes.**

Meglumine antimoniate-containing liposomes with reduced size were prepared as described previously (38). Briefly, small unilamellar vesicles (SUVs) were obtained by ultrasonication of a suspension of multilamellar vesicles in de-ionized water, made from DSPC, CHOL and DCP (molar ratio of 5:4:1) at the final lipid concentration of 55 g/L. After filtration through sterile 0.22 µm membrane, the SUVs suspension was mixed with sucrose at a sugar/lipid mass ratio of 3:1 and a final sugar concentration of 0.3 M. The resulting mixture was immediately frozen in liquid nitrogen and subsequently dried (freeze-dryer, 4.5 L, Labconco, UK). Rehydration of the dried powder was performed with a meglumine antimoniate aqueous solution (antimony concentration of 0.65 M) and phosphate-buffered saline (PBS: 0.15 M NaCl, 0.01 M phosphate, pH 7.2) as follows: 40 percent of the original SUVs volume of meglumine antimoniate solution was added to the lyophilized powder and the mixture was vortexed and incubated for 30 min at 55°C; the same volume of PBS was then added and the mixture was vortexed and incubated for 30 min at 55°C. Drug-containing liposomes were separated from non-encapsulated drug by centrifugation (14,000Xg, 30 min). The liposome pellet was then washed twice and finally resuspended in isotonic saline at a final antimony concentration of about 10 g/L. The concentration of encapsulated antimony and the phospholipid concentration were determined in the resulting liposome suspension, using previously described colorimetric assays (34, 38). The drug encapsulation efficiency and the final Sb/lipid ratio were equal to 40±4% and 0.25:1 (w/w), respectively. The final vesicular suspension was sized by photon correlation spectroscopy at 25°C with a 90° scattering angle and using a channel correlator (ZEN3500, Malvern Instruments, UK).
in conjunction with a laser of wavelength 532 nm. The mean hydrodynamic diameter of the
vesicles was 400 nm, with a mean polydispersity factor of 0.3. Empty liposomes with a
comparable mean hydrodynamic diameter were obtained using the same method as that described
above, except that the meglumine antimoniate solution was replaced by a 0.65 M N-methyl-D-
glucamine aqueous solution at pH 7.2.

**Treatment protocol.** Thirty-six dogs were stratified by weight, sex and clinical forms and
randomly distributed into three groups, each group containing initially 4 asymptomatic, 4
oligosymptomatic and 4 symptomatic dogs (26). Group I was treated with four doses of liposomal
meglumine antimoniate at 6.5 mg Sb/kg/dose given with 4 days-intervals. Group II received four
doses of antimony-free liposomes given at the same lipid dose as in group I. Group III received 4
doses of isotonic saline given at the same volume as in group I. The animals were clinically
monitored during the five months of experiment and were euthanized 150 days after treatment
with a lethal dose intravenous of Thiopental®. The mean value of the clinical state in each animal
group was calculated, by assuming values of 1, 2, 3 and 4, for asymptomatic, oligosymptomatic,
symptomatic dogs and dogs submitted to euthanasia due to disease evolution, respectively.

**Toxicity Studies.** The animals from groups I, II and III were evaluated for clinical and behavioral
changes as well as for changes in some hematological and biochemical markers of hematopoietic,
hepatic and renal functions before and four days after treatment. Temperature, food and water
intake were registered and heart and respiratory frequencies were measured. Blood samples were
taken from the cephalic vein, contralateral to that used for infusion, for analysis of haemogram
(red blood cells, packed cell volume, haemoglobin, white blood cells, neutrophils, lymphocytes,
monocytes, eosinophils and platelets), renal profile (urea and creatinina) and hepatic profile
(aspartate aminotransferase, alanine aminotransferase, alkaline phosphatase and total bilirubins).
In another independent experiment, toxicity was evaluated in mongrel dogs with VL following a single dose of liposomal meglumine antimoniate. These animals received an intravenous bolus injection of the liposome formulation at 4.2 mg Sb/kg of body weight and were sacrificed 24 h (3 animals), 48 h (3 animals), 72 h (3 animals) and 96 h (5 animals) after administration. The dogs were monitored continuously for clinical alterations. Laboratory parameters were evaluated at the specified time intervals, as described above.

**Parasitological Evaluations.** Immunocytochemical (ICH) evaluation for *Leishmania* tissue burden was carried out after euthanasia of animals, as described previously (25). Briefly, samples of ear skin, bone marrow, cervical lymph node, spleen and liver were collected and fixed in 10% neutral buffered formalin solution. All tissue samples were dehydrated, cleared, embedded in paraffin, cut into 4–5 µm thick sections for immunocytochemical studies. Deparaffinated slides were hydrated and incubated with 4% hydrogen peroxide (30, v/v) in 0.01 M PBS, pH 7.2, followed by incubation with normal goat serum (diluted 1:50). Heterologous immune serum from dogs naturally infected with *L. chagasi* (diluted 1:100 in 0.01 M PBS) was used as the primary antibody. The slides were incubated for 18–22 h at 4°C in a humid chamber, washed in PBS, incubated with biotinylated goat anti-mouse and anti-rabbit (Link-DAKO, LSAB2 kit, California, USA), washed once more with PBS and incubated with streptavidin-peroxidase complex (Link-DAKO, LSAB2 kit, California, USA) for 20 min at room temperature. The reaction was developed with 0.024% diaminobenzidine (DAB: Sigma, Saint Louis, USA) and 0.16% hydrogen peroxide (40, v/v). The slides were counterstained with Harris’s hematoxylin, dehydrated, cleared and mounted with coverslips. The *Leishmania* tissue burden was determined from the count the immunolabeled amastigotes in twenty microscopic fields randomly chosen.
Giemsa-stained sternal bone marrow aspirates were also obtained from animals in each group, 4 days after treatment, and used for the determination the number of amastigotes/1000 cell nuclei. Giemsa-stained impression smears of spleen were obtained from all animals after euthanasia and the LDU was calculated as the number of amastigotes per 1000 host cell nuclei X organ weight in grams.

**Xenodiagnosis.** The *Lutzomyia (L.) longipalpis* phlebotomines used in the present study belonged to generations F1 and were kindly provided by Dr. Edelberto Santos Dias, Institute Research Renée Rachou, Fundation Oswaldo Cruz (FIOCRUZ), Belo Horizonte, Minas Gerais, Brazil. The xenodiagnosis was realized as previous described (15). In brief, sand flies were fed on dogs by putting the insects in a specially designed receptacle (FleboContainer). Approximately 40 females and about 20 males were used in each experimental replicate. During 40 min in a darkened room, the FleboContainer netting was placed in direct contact with the medial skin of the dog’s right ear (43) previously sedated with 0.8 or 1.2 mL/kg of acepromazine (Univet). After feeding, the insects were returned to the insectary for five days and provided with a solution of fructose in distilled water (50:50 v/v) and kept at 28°C. Five days after feeding, live male and female sand flies were counted and the engorged females dissected in a drop of PBS. The guts were examined under interference microscopy (24) and the proportions of infected females and appearance of flagellates within the digestive tract of each sand fly were recorded. The approximate numbers of promastigote and their distribution in different parts of the gut were estimated based on observations using the 40X objective of a microscope. The intensity of infection was classified as “low” when few promastigotes were seen in the sand fly midgut with little or no motility. It was classified as “medium” when many motile promastigotes where seen in the fore- and midgut and...
as ‘high’ intensity infections, when large numbers of promastigotes were seen throughout the gut and rosettes of parasites were visible (15).

**Statistical analysis.** Comparisons of tissue parasitic loads between two groups were performed by Mann-Whitney Test or Student’s Test, while those between three groups were carried out using ANOVA or Kruskal-Wallis tests, followed by Tukey’s or Dunn's Multiple Comparison Test. Fisher’s exact, Qui-square and Kruskal-Wallis tests were used to compare the clinical states of animals between the different groups. The analysis of correlations between variables (i.e. between clinical condition, parasite load and infectivity of dogs to sand flies) was performed by the method of Spearman. The Qui-square test was used to compare the efficiencies of infected sand flies between different groups. All statistical analyses were performed using Prism 3.0 and Minitab 14 softwares (95% significance level).

**RESULTS**

**Impact of treatment with liposomal meglumine antimoniate on clinical parameters.**

Treatment of mongrel dogs naturally infected with *Leishmania (L.) chagasi* was performed with either liposomal meglumine antimoniate (group I, n = 12, 4 doses of 6.5 mg Sb/kg with interval of 4 days between each dose), antimony-free liposomes (group II, n = 12, liposomes given at the same lipid dose as in group I) or saline (group III, n = 12). In the present study, after inclusion of animals according to laboratory, serological and parasitological criteria, those were classified according the clinical exams as asymptomatic, oligosymptomatic or symptomatic, as described previously (26). Since the clinical condition of the dogs is expected to influence the response to
treatment (6, 26), the different groups were designed such as to be constituted initially of the same proportion of dogs in each category (4 animals of each category), as shown in Figure 1. Before treatment, the main clinical signs were lymphadenopathy, alopecia, dull fur, exfoliative dermatitis and skin ulcers, in decreasing order of occurrence. In all animals exhibiting clinical signs of the disease, the lymph nodes showed also size increase, with a higher frequency for cervical ones, followed by the popliteal and submandibular nodes.

As illustrated in Figure 1, during the experiment, nine animals were submitted to euthanasia either because of the disease evolution (8 dogs) or because of lesions resulting from fights (1 dog).

As shown in Figure 1, the initial condition of animals was found to be altered 30 days after treatment in all three groups. The disease showed an absence of evolution or an evolution towards higher intensity in the animals of groups II and III. On the other hand, animals from group I showed a variable response. Among initially symptomatic animals in group I, three showed a considerable remission of the clinical signs after 30 days which permitted their re-classification as oligosymptomatic. Among initially oligosymtomatic animals in group I, one showed a positive response to treatment and did not show clinical signs of the disease in any subsequent evaluations and two dogs showed a negative evolution of the disease (one subsequently submitted to euthanasia and the other re-classified as symptomatic). Among initially asymptomatic animals in group I, one remained as asymptomatic 30 days after treatment, two changed to oligosymptomatic and one to symptomatic. The positive impact of the treatment with liposomal Sb was also revealed, after 30 days, from the lower mean value of the clinical state of group I, compared to those of groups II and III (Figure 1). Although the mean values of dog clinical state did not differ significantly between animal groups, group I showed a significantly higher number of animals with clinical state lower than 3, when compared to group II ($P<0.05$, Fisher’s exact test).
after treatment, the clinical status was maintained in groups II and III, whereas the animals of group I showed a worsening of the clinical status. At the end of the experiment, all groups were found to be equivalent with respect to their clinical status.

5 **Toxicity evaluations.** The group that received multiple doses of liposomal meglumine antimoniate was compared to those that received antimony-free liposomes and saline. Side effects were monitored clinically in each animal during the initial hour after each of the four doses given at 4-day intervals (total of 48 recordings per group). Although in the control group (saline) no adverse effect was observed, undesired effects were observed in 90% and 77% of recordings in the groups receiving liposomal meglumine antimoniate and empty liposomes, respectively. These adverse reactions were observed only during the first 15 min after dosing with the liposomal formulations and varied from discrete tachycardia and/or tachypnea to clinical manifestation of tachycardia, tachypnea, salorrhea and mydriasis, followed by miosis, prostration, urination, muscle tremor, vomiting and defecation.

10 Serum markers of the hepatic (aspartate aminotransferase, alkaline phosphatase, alanine aminotransferase, total bilirubins) and renal functions (urea, creatinina) did not show significant changes in all groups, when comparing their levels before and four after treatment. In addition, evaluation of the haemogram parameters in treated groups showed no suppression of the hematopoietic function (data not shown).

20 In another experiment performed with 14 additional mongrel dogs with VL evaluated for short-time side effects of a single dose of liposomal meglumine antimoniate (4.2 mg Sb/kg by iv route), the haemogram and the levels of the markers of hepatic and renal functions showed no significant changes 24, 48, 72 and 96 hours after administration (data not shown).
Impact of treatment on tissue parasite burden. Figure 2 displays the mean number of amastigotes/1000 host cell nuclei determined from aspirates of the sternal bone marrow of dogs in each group, 4 days after the end of treatment. In group I, the presence of parasite was observed in only one animal out of twelve (8.3%). In groups II and III, parasites were encountered in 60% (n = 10) and 66% (n = 12) of animals, respectively. Statistical analysis indicated a significantly lower parasite burden in group I, when compared to groups II and III (P<0.05, Kruskal-Wallis).

Figure 3 shows the results obtained from immunocytochemical evaluations for *Leishmania* burden in the skin, cervical lymph nodes, bone marrow, liver and spleen, carried out 150 days after treatment. Statistical analyses indicated significantly lower parasite burdens in the lymph nodes, liver and spleen of group I, when compared to groups II and III (P<0.05, Kruskal-Wallis). Strikingly, no parasite was detected in the liver and lymph nodes in animals of group I, whereas at least 60% of animals of groups I and III were found to be positive for *Leishmania* amastigotes in the same tissues (with at least one parasite in twenty microscopic fields). According to these data, more than 95.7% reduction of the parasite burden was achieved in the liver, spleen and cervical lymph nodes following treatment with liposome-encapsulated drug, when compared to treatment with either saline or empty liposomes. It is also noteworthy that only group I exhibited animals (2 out of 9) which were parasitologically negative in all analyzed tissues. One of these animals was oligosymptomatic and the other one symptomatic.

As shown in Figure 3, the spleen of dogs was evaluated both immunocytochemically and by Giemsa-staining. In both cases, a significant reduction of spleen parasite burden was observed in group I, when compared to groups II and III (P<0.05, Kruskal-Wallis). The dog from group I that was positive according to both assays was found to be oligosymptomatic.
Importantly, none of the treated animals showed complete elimination of *Leishmania* parasites, as evidenced by *in vitro* culture of bone marrow aspirates 150 days after treatment (data not shown).

**Impact of treatment on the infectivity of dogs to sand flies.** Table 1 shows the intensity and percentage of infection of *Lutzomyia longipalpis* females fed on the dogs of the different groups, 150 days after treatment. At the end of the experiment, it was possible to visualize the promastigotes in the digestive tract of the fed phlebotomines in 10 out of 29 animals (34.5%) submitted to the xenodiagnosis. Among the 10 dogs that were infective, 1 belonged to group I (n = 9, 11%), 5 to group II (n = 11, 45%) and 4 to group III (n = 9, 44%). The infection efficiency of phlebotomines, given by the ratio of infected phlebotomines per fed phlebotomines, was equal to 0.65%, 14.3% and 21.5%, in groups I, II and III, respectively. Strikingly, the infection efficiency of phlebotomines in group I was found to be significantly lower than that in the other groups ($P < 0.01, \chi^2$ test).

**DISCUSSION**

The present study reports the toxicity and antileishmanial efficacy of a novel liposomal formulation of meglumine antimoniate in mongrel dogs naturally infected with *Leishmania* (*Leishmania*) *chagasi*. This represents a continuation of our previous work which led to the design and the pharmacokinetic characterization of the novel liposomal formulation (20, 37, 38, F. Frézard, C. Demicheli, D. A. Schettini, R. R. Ribeiro, M. N. Melo, and M. S. M. Michalick, November 2004, Brazilian Patent Pending). As main advantages, this formulation can be stored in...
an intermediate lyophilized state and consists in vesicles with mean diameter in the nanometer range allowing for safer intravenous administration and improved targeting to the bone marrow (38). The dosage and interval between the doses used in the present study were chosen from pharmacokinetic data determined previously in dogs with VL (38), indicating that high levels of Sb were maintained in the liver and spleen from 24 to 96 hours following a single i.v. administration of the liposomal formulation (at 4.2 mg Sb/kg).

Based on hematological parameters and serum biochemical markers, no significant alteration of the hematopoietic, renal and hepatic functions of dogs could be detected, either within the 96 hours following a single dose of the liposome formulation or after the administration of the four consecutive doses. On the other hand, transitory acute side effects, including prostration, defecation, tachypnea and sialorrhea, were observed during the 15 min following every administration of the liposomal formulation. Since similar side effects were also observed after the administration of empty liposomes, those could be attributed to a reaction toward the vesicles but not the metal. Indeed, lipid vesicle-induced acute adverse reactions have been reported previously and were attributed to the activation of the complement system (40). Those were named complement-mediated pseudo-allergic reactions. The cardiopulmonary alterations usually initiated just after the infusion of liposomes most probably arise from the action of complement products, presumably the anaphilatoxins C3a and C5a, which cause an increase of the pulmonary arterial pressure, a reduction of the cardiac debit (40, 41), as well as an increase of pulmonary and peripheral vascular resistance.

According to the present work, treatment of infected dogs with 4 doses of liposomal meglumine antimoniate led to a partial clinical recovery, which was not observed in the dogs treated with saline or empty liposomes. A significant reduction of bone marrow parasite burden
was observed four days after the end of treatment. Importantly, five months after the treatment, significantly lower parasite loads were found in cervical lymph nodes, liver and spleen of animals treated with the liposomal drug formulation, indicating a long-term reduction of the parasite load of these tissues. The immunocytochemical evaluation of the proportion of positive dogs five months after treatment showed significant differences between group I and the other groups, when considering the lymph nodes, liver and spleen, but not the bone marrow and skin. The apparently lower efficacy of liposomal meglumine antimoniate for parasite suppression in the bone marrow and skin may be explained by the fact that these tissues are less accessible to the liposomes. Our previous observation that Sb levels in the bone marrow of dogs with VL were about 10-fold lower than those in the liver and spleen (38), following administration of the same liposomal formulation in dogs naturally infected with *Leishmania chagasi*, is consistent with this interpretation. Another interesting observation of our previous pharmacokinetic study was that equivalent Sb levels were found in the liver and spleen of infected dogs (38), during the four days following administration of the liposome formulation. On the other hand, significantly different levels of parasite suppression were achieved in the liver and spleen 150 days after treatment (100% and 95.7%, respectively; *P*<0.05, Kruskal-Wallis test). These data taken altogether suggest a lack of correlation between tissue parasitic load and Sb concentration. This observation is not surprising, since a previous study in a mouse model of *L. donovani* infection has indicated that sodium stibogluconate, either free or encapsulated in liposomes, was effective in reducing parasite burden in the liver but not in the spleen (11), indicating that the drug antileishmanial activity is organ-dependent. Different intra-organ drug distributions and/or levels of activation of tissue *Leishmania*-infected macrophages may account for this effect. In the case of liposomal drug formulations, another factor that may contribute to the poor correlation between parasite
load and tissue drug concentration is the fact that a large proportion of the drug determined in
the organ may still be encapsulated in liposomes and, therefore, may not be bioavailable.

To our knowledge, parasitological evaluations of dogs with VL submitted to treatment with
liposome-encapsulated antimonial drug have reported in only two previous studies (12, 14, 37). In
the first study (12), liposome-encapsulated meglumine antimoniate was administered in mongrel
dogs experimentally infected with *L. donovani* (12 days after infection) at doses varying from
0.01 to 0.61 mg Sb/kg/dia during one, four and ten days. The spleen was evaluated
parasitologically four days after the end of treatment. It was verified that the formulation, when
administered at low dose, provided little reduction in the number of parasites in spleen, either
during one (31.8% suppression) or ten days (64.7% suppression) of treatment. On the other hand,
the highest dose investigated during four days of treatment showed a high (97.4%) parasitic
suppression. Although the protocol used in the present study seems, at first sight, as effective as
that used by these investigators, the use of naturally-infected dogs and the parasitological
evaluation five months after treatment make our data much more relevant to the clinical setting.

In a previous study performed by our group (14, 37), meglumine antimoniate encapsulated in
liposomes of larger size (mean diameter of 1200 nm) has been evaluated for its efficacy in
naturally-infected mongrel dogs, using a similar protocol (4 doses of 6.5 mg Sb/kg given with 4
days-intervals). Determination of the parasite load in the bone marrow aspirates of dogs 30 days
after the end of treatment showed a significantly lower number of positive dogs (with at least one
amastigote per 1000 host cells) in the group treated with liposomal drug, when compared to the
control groups (treated with saline and empty liposomes) (37). On the other hand, the
immunocytochemical evaluations of the spleen, four months after the end of treatment, and of the
skin of ear at various times (zero, 30, 60, 90 and 120 days after the treatment) showed no
significant difference between the groups (14). It is also noteworthy that this previous study also included, as a control, a group of animals receiving the free drug at the same dosage as the encapsulated one. As expected from the very low cumulative dose of Sb, the long time-interval between each dose (compared to conventional antimony therapy) and the low Sb accumulation in the infection sites (38), no side effect was registered and no difference between the group treated with the free drug and that treated with saline was observed, from both the clinical and parasitological points of view. These data taken altogether indicate that the liposome formulation used in the present study, which consists of vesicles with size in the nanometer range, promoted significant a long-term parasite suppression, in contrast to the drug encapsulated in vesicles of larger size and to the free drug.

As evidenced from the culture of bone marrow aspirates, *Leishmania* parasites were still detected in all treated dogs, five months after the end of treatment. Considering as rare the times where it is verified complete elimination of parasites from chemotherapy (31), it turned to be important evaluating the epidemiological risk of these animals by means of xenodiagnosis (2). Strikingly, the liposome formulation of meglumine antimoniate was found to reduce significantly the infectivity of dogs to *Lutzomyia* (*L.* longipalpis), five months after the end of the treatment. This data indicates that although the reduction of parasite load in the skin promoted by the liposomal drug was not statistically significant, it was sufficient to reduce significantly the infectivity of the dogs to sand flies.

It is noteworthy that the clinical condition of the animals did not correlate either with the parasite load of tissues or with the infectivity of dogs to sand flies (*P*>0.05, Spearman). These observations are in accordance with previous ones from other authors (22, 28, 39, 42),
demonstrating the epidemiological importance of the diverse clinical status in the transmission of the parasite.

Conventional treatments of dogs with VL using free pentavalent antimonial drugs showed high antileishmanial efficacy, promoting both suppression of tissue parasites (32) and reduction of infectivity of animals to sand flies (2, 21). Nevertheless, complete parasite elimination was rarely observed (31). It is noteworthy that the cumulative dose of antimony used in conventional antimonial treatment of infected dogs usually exceeds 500 mg of Sb/kg/treatment. This dose is at least 20-fold higher than that used in the present study. Indeed, the use of a much lower dose of antimony together with a reduced frequency of administration represents a major advantage of the liposome formulation, resulting ultimately in less pronounced metal-induced side effects.

Whether complete parasite elimination can be achieved by using a liposomal drug formulation remains an open question. In addition to the drug targeting to infection sites, liposomes may exert additional synergistic effect related to their immunoadjuvant properties, for instance by facilitating Leishmania antigen presentation to immunocompetent cells (8, 10). To improve the treatment efficacy with our liposome formulation, increasing each dose of Sb is probably not appropriate, since this will result in a lipid dose higher than 25 mg of lipid/kg of body weight (used in our study), which may increase the saturation of the liver and impair its physiological function. Indeed, the saturation of the liver by liposomes was described previously in mice and rats from lipid doses ranging from 3-10 mg of lipid/kg of body weight (23). Therefore, increasing the number of doses and thus, the duration of the treatment, should be a more effective strategy.

The data show the code number of identification the dogs in accordance with each experimental group, the percentage of infection to *Lutzomyia longipalpis* five days after feeding on dogs and the intensity of the infection by the dog, according to the number, the activity and the localization of the promastigote forms in the digestive tract of the phlebotomines: (+) low infection intensity – few promastigotes were seen in the sand fly midgut with little or no motility; (+++) medium infection intensity – many motile promastigotes were seen in the fore- and midgut; (+++) high infection intensity - large numbers of promastigotes were seen throughout the gut and rosettes of parasites were visible. GI = treatment with liposomal meglumine antimoniate, four doses at 4-day intervals at 6.5mg de Sb/kg. GII = treatment with empty liposomes four doses at 4-day intervals; GIII = treatment with isotonic saline at 4-day intervals.

**Figure 1.** Clinical status of dogs naturally infected with *Leishmania* (*Leishmania*) *chagasi*, just before treatment (T0) and 30 (T1), 90 (T2) and 150 (T3) days after treatment with different formulations. Group I: received liposomal meglumine antimoniate, as 4 doses by i.v. route of 6.5 mg Sb/kg/dose, with 4-days intervals; group II: received antimony-free liposomes as 4 doses by i.v. route of liposomes at the same lipid dose as in group I, with 4-days intervals; group III: received saline as 4 doses by i.v. route at the same volume as group I, with 4-days intervals. Numbers within brackets represent the mean values of the clinical state for each of the three groups at each time period, assuming values of 1, 2, 3 and 4, for asymptomatic, oligosymptomatic, symptomatic dogs and dogs submitted to euthanasia (due to disease evolution), respectively.

**Figure 2.** Parasite burdens in the sternal bone marrow of dogs naturally infected with *Leishmania* (*Leishmania*) *chagasi*, 4 days after treatment with different formulations. Group I: received liposomal meglumine antimoniate, as 4 doses by i.v. route of 6.5 mg Sb/kg/dose, with 4-days intervals; Group II: received antimony-free liposomes as 4 doses by i.v. route of liposomes at the same lipid dose as in group I, with 4-days intervals; Group III: received saline as 4 doses by i.v. route at the same volume as groups II and III, with 4-days intervals. Parasite burden = amastigote number/1000 host mononuclear cell nuclei. Data are given as mean ± standard error (n = 10 - 12). *P* < 0.05, Kruskal-Wallis, followed by Dunn's Multiple Comparison Test, for comparison between GI and GII, GI and GIII.
Figure 3. Parasite burdens in the skin (A), bone marrow (B), cervical lymph nodes (C), liver (D) and spleen (E, F) of dogs naturally infected with *Leishmania* (*Leishmania*) *chagasi*, 150 days after treatment with different formulations. Group I: received liposomal meglumine antimoniate, as 4 doses by i.v. route of 6.5 mg Sb/kg/dose, with 4-days intervals; Group II: received antimony-free liposomes as 4 doses by i.v. route of liposomes at the same lipid dose as in group I, with 4-days intervals; Group III: received saline as 4 doses by i.v. route at the same volume as groups II and III, with 4-days intervals. A, B, C, D, E: parasites were determined immunocytochemically as described in the Materials and Methods section and parasite burden = number of *Leishmania* parasites per 20 microscopic fields. F: parasites were determined through Giemsa staining and LDU index = number of amastigotas per 1000 host cell nuclei X organ weight in grams. Data are given as mean ± standard error (n = 9 - 11). *P*<0.05, Kruskal-Wallis, followed by Dunn's Multiple Comparison Test, for comparison between GI and GII, GI and GIII.
